Relation of cervical cytologic evaluation to clinical and immunologic status of HIV infection. Nearly 50% of the women with HIV-seropositive test results had generalized lymphadenopathy together with abnormal immunologic findings and were therefore classified as Centers for Disease Control stages IIIB and IV. Although four out of the five carcinomas that were detected were seen in patients with stage IV HIV disease ($p < 0.01$), there was no significant correlation of the frequency of dysplasia to the different stages of HIV disease (Fig. 1).

To define immunosuppression more precisely, T-cell

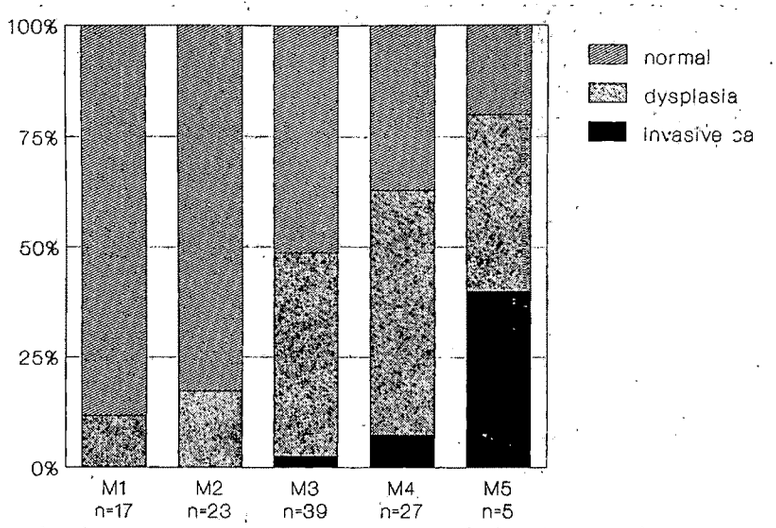

Fig. 3. Cytologic findings in HIV-infected women with defined defects in the lymphoproliferative response.

Table III. Cytologic findings in HIV-infected women with defined alterations of lymphocyte subsets

	No signs of dysplasia	*Dysplasia*	*No. with invasive carcinoma*	*Total*
T1	17 (70%)	7 (30%)		24
T2	29 (62%)	18 (38%)	1	47
T3	10 (48%)	11 (52%)		21
T4	9 (47%)	10 (53%)	4	19

Table IV. Cytologic findings in HIV-infected women with defined defects in the lymphoproliferative response

	No signs of dysplasia	*Dysplasia*	*No. with invasive carcinoma*	*Total*
M1	15 (88%)	2 (12%)		17
M2	19 (83%)	4 (17%)		23
M3	20 (51%)	19 (49%)	1	39
M4	10 (37%)	17 (63%)	2	27
M5	1 (20%)	4 (80%)	2	5
TOTAL	65 (59%)	46 (41%)	5	111

subset counts were performed, and parameters of lymphocyte function were determined. The frequency of dysplasia-neoplasia at defined alterations of T-cell subsets is shown in Fig. 2 and Table III. Again four of the five carcinomas that were detected were seen in patients with the most pronounced $CD4^+$ cell depletion (>250/μl) ($p < 0.01$). The apparent correlation of dysplasia and lymphocyte depletion is statistically not significant ($p = 0.2$) because of the small number of patients. However, a highly significant correlation of cervical dysplasia or invasive carcinoma with functional immunosuppression as determined by assays of lymphocyte proliferation (M1 to M5) could be demonstrated ($p < 0.01$; Fig. 3 and Table IV).

Comment

In this study the frequency of cervical dysplasia-neoplasia and signs of HPV infection were compared in three groups of women of similar age. Baseline data that were obtained in 526 women from the outpatient

population were related to data that were obtained from HIV-infected women and HIV-negative female intravenous drug users. The two latter groups were equally promiscuous and therefore had a comparable risk of HPV infection.

HIV-infected women had a tenfold higher prevalence of dysplasia-neoplasia than the outpatient population and a still fourfold higher prevalence of dysplasia-neoplasia than HIV-negative female intravenous drug users.

Several findings point to a role of HPV in the cause or development of cervical dysplasia-neoplasia.[19-21] The reported high prevalence of latent HPV infection in populations of healthy women suggests that HPV infection by itself may not be sufficient to cause the development of cervical dysplasia or cancer.[22] The increased manifestation of active HPV infection as proved by the presence of koilocytes or dyskaryocytes in 81% of HIV-infected patients with dysplasia-neoplasia suggests an HIV-induced impairment of cellular immune response. In addition to established cofactors such as sexual activity, frequent genital infections, and smoking habits, which are frequently found in this group, we propose HIV-induced immunosuppression as another important cofactor in the risk of dysplasia/neoplasia. The observation that HIV-infected but immunocompetent women showed a prevalence of dysplasia/neoplasia that was comparable to the prevalence seen in HIV-negative women with a comparable risk for HPV infection argues against a mere synergistic interaction between HIV and HPV, as suggested for herpes simplex viruses and HIV.[23]

In our study the impairment of lymphocyte functions was significantly correlated with an increasing risk for cervical dysplasia/neoplasia. A comparable explanation has been proposed by other authors who found an increased prevalence of cervical cancer in women who were immunocompromised by Hodgkin's disease[24] or who had iatrogenic immunosuppression after renal transplantation.[25]

These interpretations are supported by studies that demonstrate that in animal models cell-mediated immune responses directed against viral or virally induced antigens represent the major effector mechanism in the control of papillomavirus infections.[26] It is therefore tempting to speculate that the HIV-induced immunodeficiency may lead to an active chronic HPV infection and thereby to persistence or progression of dysplasia. The correlation of cervical dysplasia and invasive carcinoma to the degree of immunologic impairment in HIV-infected women raises the question of whether HPV-induced dysplasia/neoplasia should be considered as an opportunistic disease.

As a consequence, clinical surveillance of HIV-infected women should include cytologic investigation of the uterine cervix at regular intervals; the frequency depends on the stage of HIV disease. The high proportion of suspicious colposcopic findings and the observed severity of cervical intraepithelial neoplasia in HIV-infected women demand careful colposcopic examinations and immediate directed biopsy when indicated. This is especially important in intravenous drug users who show a low compliance with the need for regular medical checkups.

Characterization of enzymes of catecholamine synthesis and metabolism in human fetal membranes at birth

Viviane Casimiri, PhD,[a] Germaine Acker, PhD,[b] Simone Parvez, PhD,[a] Hasan Parvez, PhD,[a] Lony Castro, MD,[c] Calvin Hobel, MD,[c] and Emile Papiernik, MD[b]

Orsay and Clamart, France, and Los Angeles, California

We looked for the presence of the enzymes monoamine oxidase, catechol-O-methyltransferase, and phenylethanolamine-N-methyltransferase in human fetal membranes at term. The activity of all three enzymes was detected via highly sensitive and selective radiometric enzyme assays. The most novel finding was the extremely high level of monoamine oxidase activity in the chorion compared with that in the amnion. The other enzyme of catecholamine metabolism, catechol-O-methyltransferase, did not show any difference in activity between the two layers. In addition, we observed that the enzyme phenylethanolamine-N-methyltransferase, which is primarily located in the adrenal medulla, was also present in appreciable levels in the two layers of fetal membranes. These results suggest that fetal membranes, like the placenta, possess the enzymatic machinery to metabolize catecholamines and have the capacity to synthesize epinephrine. (Am J Obstet Gynecol 1991;164:599-603.)

Key words: Enzymes for synthesis and metabolism, catecholamines, chorion, amnion

The participation of adrenergic innervation in the maturation of fetal development has been looked on critically by several groups.[1, 2] Numerous studies have analyzed extensive biochemical and neuroendocrine factors that can lead to fetal delivery at term.[3] The focus of these studies has been the importance of the uterus and the placenta. Neurochemical exploration of the placenta suggests that this organ contains most of the inactivating enzymes necessary to deliver physiologic concentrations of different transmitters and hormones. It has also been established that placental tissue possesses significant levels of two enzymes, monoamine oxidase (MAO) and catechol-O-methyltransferase (COMT), which are involved in catecholamine metabolism.[4] Fig. 1 depicts a general overview of catecholamine biosynthesis and metabolism. The significance of MAO and COMT in the inactivation of catecholamines from the maternal circulation can be shown by perfusion of labeled catecholamines to the mother and their detection in the fetus.[5] Placental tissue apparently serves as a barrier to prevent excessive levels

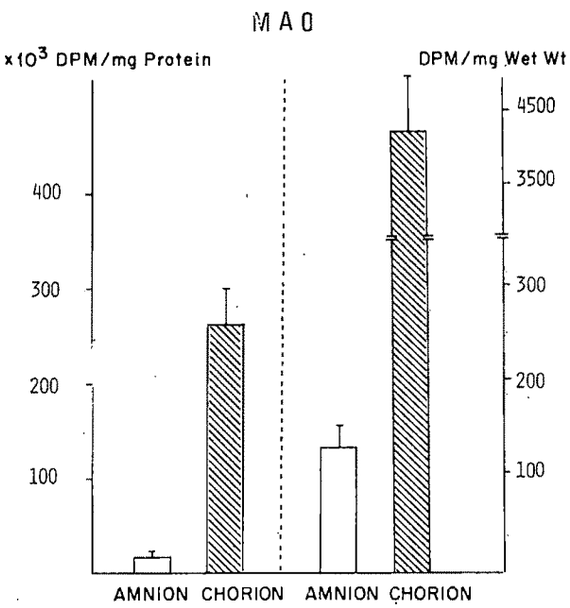

Fig. 2. Activity of enzyme MAO in two layers of fetal membranes. Activity has been expressed per milligram protein, as well as per milligram wet weight. MAO activity was significantly greater in chorion than in amnion ($p < 0.001$, $n = 10$).

of norepinephrine and epinephrine from crossing the maternal circulation to the fetus.

The presence of catecholamines and their metabolites in fetal amniotic fluid has been observed in our laboratory, as well as by several other authors. These studies indicated that levels increase with gestational age and labor.[6,7] Studies by Phillippe et al.[8] support a role for the fetal membranes in the metabolism of catecholamines. In addition, our recent studies show a strong modulation of prostaglandin secretion by fetal membranes in response to catecholamine stimulation.[9] However, according to our knowledge, the neurochemical characterization of the different enzymes of catecholamine metabolism and synthesis in fetal membranes has not been previously reported. The goal of the present investigation was to identify the presence of the catecholamine metabolizing enzymes (MAO and COMT) and the synthesizing enzyme phenylethanolamine-N-methyltransferase (PNMT) in the human chorion and amnion.

Material and methods

This study was approved by the institutional review board of the Maternite Hopital Antoine Beclere of the University of Paris. Human fetal membranes (chorion and amnion) were obtained at the time of cesarean section from 10 women in labor at term. The membranes were rapidly dissected into chorion and amnion and were stored at −80° C until assayed. Both the amnion and the chorion were homogenized in isotonic potassium chloride at a concentration of 400 mg/ml. The homogenate for MAO assays was further diluted 10 times with isotonic potassium chloride. One part of the concentrated homogenate was centrifuged at 35,000 *g* for 30 minutes at 4° C for the preparation of cytosol for the assays of the enzymes PNMT and COMT.[10]

MAO assay. The total activity of MAO was determined by use of tryptamine-^{14}C-bisuccinate as substrate (specific activity, 49.6 mCi/mmol, New England Nuclear, Boston). The assay was adapted to be performed in disposable 1 ml polypropylene microtubes, and its sensitivity was increased. The incubation mixture consisted of 100 μl of phosphate buffer (0.1 mol/L, pH 7.4), 50 μl of diluted tissue homogenate (40 mg/ml), and 50 μl of tryptamine-^{14}C-bisuccinate (1 nmol). The tubes were incubated for 20 minutes at 37° C. The reaction was stopped by transferring the tubes to an ice bath and by the addition of 20 μl of 2N hydrochloric acid and 600 μl of toluene. The assay tubes were shaken for 20 minutes on a mechanical shaker and centrifuged at 3000 *g* for 10 minutes. The top layer (400 μl) was separated with a micropipette and transferred to a miniscintillation vial containing 1.5 ml of toluene scintillation liquid. The extracted disintegrations per min-

ute represented a direct linearity with the nanomoles of ^{14}C-indole acetic acid transformed in 20 minutes.[11]

COMT assay. The enzyme COMT was determined with the use of S-adenosylmethionine-^{3}H-methyl (Center Etudes Atomic, Gif Sur/Yvette, France) as a cofactor for O-methylation of catecholamines. Again, the assay was adapted to be performed in 1 ml polypropylene disposable tubes.[12] The incubation mixture consisted of 100 μl of phosphate buffer (0.1 mol/L, pH 7.9); 10 μl of 1% magnesium choride; 50 μl of tissue supernatant as described above (400 mg/ml), 50 μl (1.11 nmol) of S-adenosylmethionine-^{3}H-methyl (45 mCi/mmol), and 10 μl of epinephrine (11.6 mg/ml). The tubes were incubated at 37° C for 1 hour. The reaction was stopped by the transfer of the tubes to an ice bath and by addition of 50 μl of 1 mol/L borate buffer at pH 10.0. Methylated products were separated by the addition of 600 μl of toluene + isoamyl alcohol (3:2) and shaking for 20 minutes. The tubes were centrifuged at 3000 *g* for 10 minutes, and 400 μl of the organic phase of the solution was extracted by a micropipette and added to 1.5 ml of scintillation solution in a minivial. The disintegration per minute represented a direct linearity with the nanomoles of methylepinephrine that formed in 1 hour.[12]

PNMT assay. The PNMT assay was very similar to that of COMT, except that magnesium chloride was not added. The substrate used was normetanephrine (50 μl of a 2 mg/ml solution). The time of incubation was 1 hour, as it was for COMT. The extraction procedure was the same as that used for COMT, except that 440 μl of organic phase was extracted. The details of the assay have been provided elsewhere.[12, 13] The extracted radioactivity was directly linear to the nanomoles of metanephrine formed in 1 hour.

The results were subjected to statistical analysis by the paired Student *t* test. The values are expressed as the mean ± SEM. A p value <0.05 was considered significant.

Results

Fig. 2 illustrates the total activity of the enzyme MAO in amnion and chorion layers of the fetal membranes. Enzyme activity was extremely low in the amnion layer, regardless of how the results were expressed. MAO activity in the chorion layer was 16-fold (per milligram protein) and 31-fold (per milligram wet weight) higher than that in the amnion layer. These elevations were highly significant ($p < 0.001$).

Fig. 3 shows the presence of activity of the enzyme COMT in the two layers of human fetal membranes. No significant difference was observed between enzyme activity in the chorion and amnion when the results were expressed per milligram protein. However, expressing COMT activity per milligram wet weight of the two layers showed a 2.3-fold higher level in the chorion than in the amnion; this difference was significant ($p < 0.05$).

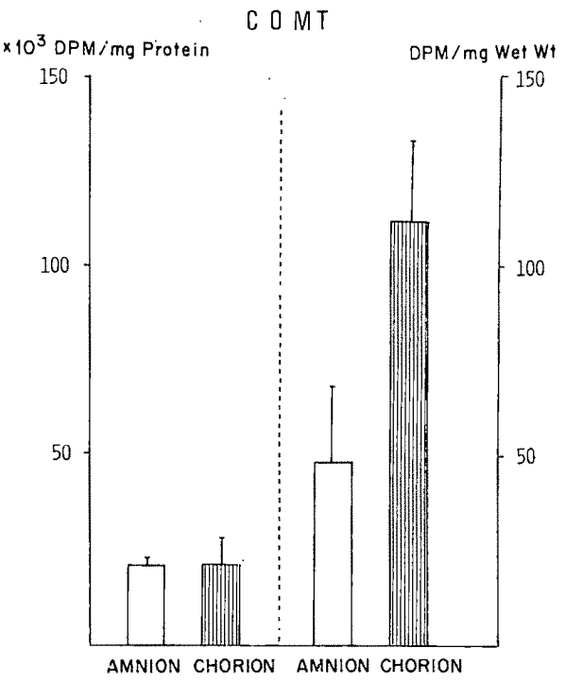

Fig. 3. Enzyme COMT in two layers of fetal membranes. COMT activity per milligram wet weight was greater in chorion than in amnion ($p < 0.05$, $n = 10$).

Fig. 4 shows the level of the enzyme PNMT in the two different layers of human fetal membranes. In the adult this enzyme is primarily confined to the adrenal medulla, but some traces can be found in other tissues. It was interesting to observe that both the amnion and the chorion contain PNMT and therefore possess the enzymatic machinery to form epinephrine endogenously. Contrary to the enzymes of catecholamine metabolism, PNMT activity in the chorion was not found to be statistically different from that in the amnion.

Comment

The results presented in this study show that the two layers of the human fetal membranes possess the enzymatic machinery to metabolize and synthesize catecholamines endogenously. These findings strengthen the hypothesis suggested by Zuspan et al.[14] in 1981, which suggests that adrenergic transmitters may play a role in parturition. The existence of the enzymes MAO and COMT in the chorion and amnion may be of great functional importance because norepinephrine and epinephrine can pass through the placental barrier and appreciable amounts of these transmitters can be localized in the amniotic fluid of human fetuses.[7, 15]

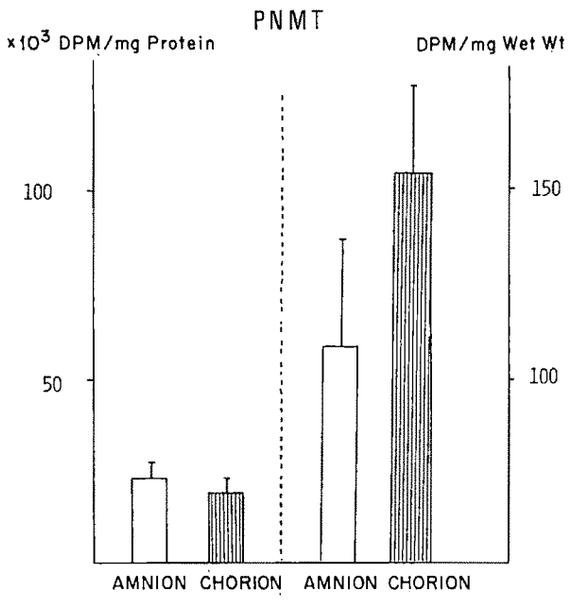

Fig. 4. Activity of enzyme PNMT in amnion and chorion layers of fetal membranes (p = NS, n = 10).

Higher concentrations of catecholamines entering the fetal circulation could be hazardous for normal fetal growth and development. On the basis of our data, it appears that the fetal membranes are equipped to exert oxidative deamination of both intracellular catecholamines and of O-methylation of circulating biogenic amines that could otherwise enter the fetal circulation. Such a process at the membrane level may provide extra protection to the preterm fetus.

The most novel finding of this investigation is the tremendous difference in the activity of the enzyme MAO in the chorion and amnion. A high content of MAO in the chorion suggests that intracellular oxidative deamination may be the most important pathway of transmitter inactivation in the chorion layer of fetal membranes.

Biochemical studies performed in vitro also suggested that the human chorioamnion has the capacity to rapidly metabolize labeled dopamine to dihydroxyphenylacetic acid, 3-methoxy,4-hydroxyphenylacetic acid, and 3-methoxy,4-hydroxyphenylethanol.[8] Phillippe and Niloff[8] speculated that the presence of catecholamine metabolizing enzymes in the chorioamnion could be responsible for the rapid conversion of labeled dopamine to different metabolites.

This study supports these conclusions. Another study that shows an increase in catecholamines and metabolites in the amniotic fluid compartment from middle to late gestation agrees with our data on the localization of MAO and COMT in the chorion and amnion layers of human fetal membranes.[7] It is necessary to characterize the different forms of the enzyme MAO in the chorion and amnion to identify specific participation of different metabolic pathways in each layer of the fetal membranes in early and late pregnancy. Such a study could clarify the results obtained in vitro with irreversible inhibitors of MAO.[8] The use of clorgyline (an MAO-A inhibitor) and deprenil (an MAO-B inhibitor) can distinguish the physiologic participation of dopamine from that of norepinephrine or epinephrine. Normally, the human fetal placenta contains only MAO-A and the placenta has very close structural similarities to the chorioamnion since both these tissues lack innervation. Therefore elucidation of the specific pathway involved in catecholamine metabolism could be useful in understanding the effects of catecholamines on fetal well-being and development.

The existence of PNMT in the amnion and chorion at trace levels suggests that fetal membranes have the capacity to undergo N-methylation of norepinephrine to epinephrine. This process may be useful in controlling the vasoactive response that could develop during excessive placental transport of catecholamines to the fetal circulation. The formation of epinephrine by fetal membranes may also modulate prostaglandin secretion, thus providing a stimulus for the onset of labor.[9]

In summary, the results of this study indicate that human fetal membranes have the capacity to metabolize and synthesize catecholamines. The most interesting finding is the large difference in MAO activity between the chorion and amnion. Isolation of the specific forms of MAO present in the amnion and chorion at different stages of gestation is necessary for interpretation of the role of this enzyme during fetal growth and development and during labor.

We thank the clinical staff of Maternite Hopital Antoine Beclere for their kind participation and supply of clinical material. The generous help from and supply of high-performance liquid chromatography columns by Jean Louis Millet, Prolabo, France, are gratefully acknowledged.

Pregnancy-related mortality in New York City, 1980 to 1984: Causes of death and associated risk factors

Carla J. Syverson, CNM, MN, MPH,[a, d] Wendy Chavkin, MD, MPH,[b] Hani K. Atrash, MD, MPH,[c] Roger W. Rochat, MD,[a] Elizabeth S. Sharp, CNM, DrPH,[d, e] and Gail E. King, MD, MPH[a]

Atlanta, Georgia, and New York, New York

To identify causes and risk factors for pregnancy-related mortality in New York City, we analyzed 224 pregnancy-related deaths that occurred from 1980 to 1984. The leading causes of death were ectopic pregnancy complications, embolism, intrapartum cardiac arrest, and hypertension. Mortality ratios were determined by comparing the characteristics of the women whose death was pregnancy-related with those of women who had survived delivery of a live infant in New York City during the same period. Black and Hispanic women had mortality ratios that were respectively 4.2 and 2.0 times higher than those for white, non-Hispanic women. In comparison with women aged 20 to 24, those older than 30 were more than twice as likely to die from pregnancy-related causes, and those older than 40 were five times as likely to do so. Other factors that were associated with an increased risk of pregnancy-related mortality included 9 to 11 years of education, lack of private medical insurance, more than five previous pregnancies, and fewer than five prenatal visits. This study suggests that changes in current maternal-health and family-planning services will be required to achieve further reductions in preventable pregnancy-related mortality. (Am J Obstet Gynecol 1991;164:603-8.)

Key words: Pregnancy, embolism, ectopic pregnancy, anesthesia

Since 1915, the pregnancy-related mortality ratio (pregnancy-related deaths per 100,000 live births) has declined in the United States, from 700 in 1915[1] to 7.8 in 1984.[2] Although this overall decline has been dramatic (approximately 90% over 70 years), there has been an insignificant decrease since 1980.[2-6]

Pregnancy-related mortality ratios in the northeastern United States and in countries such as Ireland, the Netherlands, Scandinavia, and Switzerland have been reduced to between 4 and 5 per 100,000 live births.[7] Several researchers describe significant underreporting of cases and have found the actual rate of pregnancy-related mortality to be from 39% to 112% above that reported,[8-13] which would place the true United States pregnancy-related mortality ratio between 10.8 and

Table I. Pregnancy-related mortality ratios, New York City and United States, 1980 to 1984*

Year	New York City		United States (ratio)
	No. of deaths	Ratio	
1980	55	51.4	9.2
1981	44	40.5	8.5
1982	47	42.2	7.9
1983	50	43.6	8.0
1984	28	24.7	7.8
1980–1984	224	40.2	8.2

*Pregnancy-related deaths per 100,000 live births.

16.5. One of the 1990 objectives of the United States Public Health Service is to achieve a pregnancy-related mortality ratio of 5 deaths per 100,000 live births.[14]

The major causes of pregnancy-related deaths in the United States have been attributed to the classic triad of hemorrhage, pregnancy-induced hypertension, and infection.[15] More recent studies indicate a change in this pattern, because embolism, ectopic pregnancy complications, and cardiomyopathy account for increasingly larger proportions of pregnancy-related deaths.[11, 12, 16, 17]

Risk factors for pregnancy-related death have received little attention in the literature. Previous studies have consistently shown minority women to have a pregnancy-related mortality ratio that is three to four times higher than that of white women.[11, 16-18] Kaunitz et al.[16] found women older than 30 to be at greater risk for pregnancy-related death than are younger women.

In this article we present the results of an investigation of all pregnancy-related deaths reported in New York City from 1980 through 1984 in different subgroups of women, and we describe mortality ratios, causes of death, and risk factors for pregnancy-related mortality.

Material and methods

The Bureau of Maternity Services and Family Planning of the New York City Department of Health has long been studying pregnancy-related mortality. Pregnancy-related deaths in New York City are reported to the New York City Department of Health, where a file is maintained on each death. Complete files contain copies of the death certificate, the certificate of live birth or a certificate of termination of pregnancy, the autopsy report, the medical records, and a case summary by the Bureau's obstetric consultant. We collected data for this study by reviewing each file.

For this study, a pregnancy-related death was defined as the death of any woman, from any cause, while she was pregnant or was within one calendar year of termination of pregnancy, regardless of the length and site of pregnancy. Deaths were classified as resulting from direct, indirect, or other causes. A direct pregnancy-related death was defined as a death that resulted from the management or condition of pregnancy, labor, or delivery. An indirect pregnancy-related death was defined as a one in which pregnancy exacerbated a preexisting health condition. A death that resulted from other causes was defined as a death that occurred during pregnancy or within 1 year after the termination of pregnancy but was not considered direct or indirect (for example, death from homicide or drug overdose). We use the term pregnancy-related rather than maternal because the latter term means *pertaining to the mother,*[19] and our descriptions of deaths include deceased women, such as those who had an ectopic pregnancy or abortion, whose pregnancy did not result in birth.

Pregnancy-related mortality ratios for New York City and for the United States were calculated from vital statistics provided by the New York City Department of Health[20-24] and by the National Center for Health Statistics (Table I).[2-6]

The cause of death was determined from the autopsy report or from the medical record if no autopsy report was available. In the absence of other records the cause of death was taken from the death certificate.

All deaths were attributed to one of the causes listed in Table II. Deaths attributed to ectopic pregnancy complications included all deaths involving an ectopic pregnancy, such as mortality from anesthesia complications that occurred during surgery for ectopic rupture. Deaths from embolism included both thromboemboli and emboli caused by amniotic fluid. Deaths attributed to intrapartum cardiac arrest included complications of anesthesia (not those associated with ectopic pregnancy or elective abortion) and all deaths that resulted exclusively from cardiac arrest during cesarean section without mention of other conditions or complications. Hypertension as the cause of death included both preexisting and pregnancy-induced hypertension; only two women in the study were known to have preexisting hypertension.

We examined the following risk factors to determine their association with pregnancy-related death: age at the time of death, race, marital status, education, number of previous live births, number of prenatal visits, and source of payment for health services. The analysis was limited to these factors, which included all the information that could be obtained from the comparison group of women who survived after delivery of a live infant in New York City from 1980 to 1984. We used Woolf's method to calculate relative risks with 95% confidence intervals.[25]

Missing or unknown data for the pregnancy-related

Table II. Causes of pregnancy-related death, New York City, 1980 to 1984

Cause of death	*No.*	*%*	*Ratio**
Direct cause

*Pregnancy-related deaths per 100,000 live births.

deaths and for the live births of the comparison group were assigned values according to the frequency distribution of the known data. For example, the distribution of known data for means of payment was 18.8% self-pay, 40.9% Medicaid, and 40.3% third-party. The 75 pregnancy-related deaths for which means of payment data were missing were randomly distributed so that 18.8% (n = 14) were assigned to self-pay, 40.3% (n = 31) were assigned to Medicaid, and the remaining 40.3% (n = 30) were classified as third-party.

Live-birth data were reported with at least 90% completeness for each variable. Age, race, and marital status were reported for at least 90% of the pregnancy-related deaths. Data on education, gravidity, parity, prenatal care, and source of payment were reported in varying frequencies of >50%.

Results

Despite a decrease, which probably resulted from a reporting lag, to 24.7 in 1984, per 100,000 live births, the overall pregnancy-related mortality ratio for New York City for the years 1980 to 1984 was 40.2 deaths per 100,000 live births (Table I). Whereas the greatest number of deaths and the highest ratio were seen in 1980, little variation in these factors was noted from 1981 to 1983. The average pregnancy-related mortality ratio for New York City during 1980 to 1984 was approximately five times greater than that reported for the entire United States.

Most causes of pregnancy-related death (73.5%) were classified as the direct result of complications during pregnancy, the most frequent of which were ectopic pregnancy (13.4%), pulmonary emboli (12.9%), hyper-

†Pregnancy-related deaths per 100,000 live births.

tension (10.3%), and cardiac arrest (10.3%) (Table II). Nonobstetric infection (6.7%) and complications of preexisting cardiovascular disease (4.0%) were the most common indirect causes. Only 18 deaths were attributed to other causes, the most common of which were homicide (3.1%) and suicide (2.2%).

Risk factors for all deaths are listed in Table III. The lowest risk of a pregnancy-related death was for women who were white and non-Hispanic, 20 to 24 years of age, married, educated beyond high school, privately insured, and primiparous, and who had received medical evaluation on more than five prenatal visits. The highest risk of pregnancy-related death was among women who were black, 40 years of age or older, unmarried, educated for 9 to 11 years, had neither private insurance nor Medicaid, and who had had five or more previous live births with little or no prenatal care.

Mortality risks were lowest for women who received prenatal care in the first trimester of pregnancy and highest for women who received no prenatal care. The

differences between groups of women who received care in the first, second, and third trimesters were not statistically significant.

Comment

The average pregnancy-related mortality ratio for New York City from 1980 to 1984 appears to be much higher than the average ratio for the United States during the same period. However, this comparison must be made cautiously, since several previous studies have shown that pregnancy-related mortality has been widely underreported in the United States. Also, the various definitions of pregnancy-related mortality used in different parts of the United States prevent true comparisons between states or regions.

Differences in populations also need to be acknowledged. The social and demographic characteristics of New York City differ from those of much the United States population. On the other hand, New York City characteristics that include an immigrant population, poverty, and drug abuse prevail elsewhere and make our findings relevant to other large urban areas. Whereas racial disparity appears highest in New York City, the pattern of excessive risk of pregnancy-related death for black women is national in scope.[26]

Ectopic pregnancy complications, embolism, and hypertension were found to be the three most frequent causes of pregnancy-related death in New York City. Kaunitz et al.[16] found similar results in analyzing 2475 pregnancy-related deaths that occurred in the United States from 1974 to 1978. However, the fourth leading cause of death in their study was not cardiac arrest, as our study found, but hemorrhage.

Whereas complications of anesthesia could be confirmed from medical records or autopsy reports as the cause of death for only four cases, these complications may have been underreported. On the death certificate, autopsy report, or medical record of at least seven deaths categorized as cardiopulmonary arrest, there was some reference to possible complications from anesthesia. However, the medical records for these seven cases were either unavailable or inadequate and thus could not confirm these complications as the cause of death.

All but two deaths classified as intrapartum cardiac arrest occurred during cesarean section. The two remaining deaths occurred during labor, one after the administration of an intravenous narcotic and the other after spinal anesthesia. At least six of the 14 deaths categorized as induced abortion complications resulted from cardiac arrest during legal abortion and were thought to result from complications of anesthesia.[27]

Previous studies have shown that the risk of maternal death increases with age for both blacks and whites, although the reasons for increased risk are not clear.[26] The association of risk of maternal death with increasing age was also seen in our study. The risk of maternal death in New York City was noted to increase with parity, and greater parity is associated with greater maternal age. Age-specific data were not available to permit adjustment for age in our analyses.

Separate studies by Kaunitz et al.[16] and by Buehler et al.[28] have found that women older than 30 have higher risks for pregnancy-related deaths than do women younger than 30.[26] Our findings are consistent with these studies and also show that risk increases with each 5-year age grouping beyond 30 years. Further studies would be useful to determine if women older than 30 are more likely than younger women to have underlying conditions that complicate pregnancy.

In conclusion, these findings suggest that women in New York City continue to suffer pregnancy-related deaths that are preventable. Lack of prenatal care and of third-party insurance are clearly associated with higher pregnancy-related mortality. The effect of other risk factors, such as age, race, education, and parity, may possibly be lessened by increased use of medical services.

Preventing pregnancy by improving access to contraception could help reduce pregnancy-related deaths. The risk associated with grand multiparity underscores the urgency of providing these services.

Comparison with prior work suggests that the pattern of causes for pregnancy-related mortality is changing. From 1970 to 1985 the incidence of ectopic pregnancies in the United States more than tripled.[29] As a result, complications of ectopic pregnancy are now a leading cause of pregnancy-related death.[11, 16, 17]

Rising rates of cesarean section expose more women to the risks of anesthesia and surgical complications. The number of deaths from cardiopulmonary arrest during labor, delivery, or abortion in a population not usually considered at high risk for cardiac disease should raise concerns.

Active surveillance for pregnancy-related deaths should be encouraged and developed, so that a more accurate analysis of pregnancy-related mortality can be studied. Since any pregnancy-related death should be considered preventable, autopsies should be encouraged or required in all such cases to help determine specific causes of death.

We thank Machelle Harris, MD, and Sally Faith Dorfman, MD, MPH, obstetrics consultants to the Bureau of Maternity Services, New York City Department of Health, for reviewing the cases in this report.

Estrogen receptors in the external anal sphincter

Knut Haadem, MD,[a] Lennart Ling, MD, PhD,[b] Mårten Fernö, PhD,[c] and Hans Graffner, MD, PhD[b]

Helsingborg, Sweden

Inasmuch as anal competence in women is reduced after the age of 50 years, it may be dependent on effects of estrogens. In this study, samples of the external anal sphincter were analyzed for the presence of estrogen receptors and were found to be present at a median concentration of 5.0 fmol per milligram of protein (range, 1.9 to 13) in women (n = 7), and 1.1 fmol per milligram of protein (range, 0 to 3.2) in men (n = 7). These findings are of interest with regard to the treatment of idiopathic anal incontinence. (Am J Obstet Gynecol 1991;164:609-10.)

Key words: Anal incontinence, estrogen, estrogen receptors, external anal sphincter muscle

Maintenance of anal continence is dependent on several factors,[1] the most important of which was the tonus and contractile activity of the external and internal anal sphincter muscles. The competence of the external anal sphincter muscle is reduced with age and considerably reduced in women after the age of 50 years. One reason for this might be a decrease in the effect on the sphincters of estrogens. Because a prerequisite for this hypothesis is the presence of estrogen receptors in the external anal sphincter muscle, the present study was undertaken to ascertain whether estrogen receptors are present in this muscle.

Material and methods

The series comprised 14 patients, seven men and seven women (six of whom were postmenopausal). They all underwent abdominoperineal resection, 13 because of neoplasia and one because of inflammatory disease (Table I). In no case did the tumor involve the anus. A representative sample of the external anal sphincter muscle was taken immediately after surgery and stored at −70° C until laboratory analysis was performed.

A sample of the rectus muscle was taken from five men with a median age of 70 years (range, 52 to 78), six premenopausal women with a median age of 41 years (range, 37 to 48), and five postmenopausal women with a median age of 75 years (range, 66 to 75) to serve as controls (Table II). None of the controls had hormone-producing tumors, none was taking medication with hormones, and none of the female controls was pregnant.

Table I. Concentrations of estrogen receptors found in external anal sphincter muscle specimens

Patient characteristics			*Estrogen receptor value (fmol/mg protein)*
No.	*Sex*	*Age (yr)*

6/1/24929

1 mmol/L, pH 7.4). After centrifugation at 20,000 *g* for 10 minutes, estrogen receptor content was measured in the supernatant with an enzyme immunoassay according to the kit instructions (Abbott Laboratories, Diagnostic Division, North Chicago, Ill.). The level of assay sensitivity was 2.0 fmol/ml, and estrogen receptor content was expressed in femtomoles per milligram of protein, determined according to Lowry et al.[2]

Informed consent was obtained from all patients.

Results

As shown in Table I, both the estrogen receptor content and the proportions of values in excess of method sensitivity were significantly greater in samples from female patients than in those from male patients (median estrogen receptor value, 5.0 fmol/mg protein, range, 1.9 to 13, and median estrogen receptor value, 1.1 fmol/mg protein, range, 0 to 3.2, respectively; $2p = 0.005$, Mann-Whitney U test). Two of the samples from postmenopausal patients had estrogen receptor values >10 fmol/mg protein, whereas the only sample from a premenopausal patient had an estrogen receptor value of 2.9 fmol/mg protein.

The concentrations of estrogen receptors in the rectus muscle are presented in Table II. No difference was found between sexes or between premenopausal and postmenopausal women. However, in females a significantly higher ($2p = 0.005$) estrogen receptor concentration was found in the external and sphincter than that in the rectus muscle. In the males, estrogen receptor concentrations in the rectus muscle were in the same low range as those of the external anal sphincter.

Comment

Anal continence is a complex function that involves a number of factors such as fecal consistency, anal sphincter strength, anorectal angle, and neurologic function.[1] Although fecal incontinence is a very troublesome condition for those affected, its incidence is low—a figure of 0.8% was reported for the Swedish population. The condition is usually a result of anal surgery, neurologic disease, or tears during delivery. However, in many patients direct association with a trauma or disorder cannot be found.[1] Therefore some sort of progressive pathophysiologic reduction of the contractile activity in the anal sphincter seems to take place in these patients. Because anal incontinence predominantly occurs among postmenopausal women in whom a physiologic decrease in anal competence is known to take place after the age of 50 years, it is postulated that the anal sphincter is subject to effects by estrogens.

Although the present results were obtained in a small series, it is clear that the anal sphincter muscle in females does contain estrogen receptors. This finding is in accord with reports from studies of the urethra, in which estrogen receptors have been found and considered important to the occurrence of urinary incontinence in women of postmenopausal age.[3] However, the significance of the present findings needs to be further investigated before its clinical impact can be determined. Such investigations are in progress.

Prognostic factors in gestational trophoblastic tumors: A proposed new scoring system based on multivariate analysis

John R. Lurain, MD,[a] Lisa A. Casanova, MD,[a] David Scott Miller, MD,[a] and Alfred W. Rademaker, PhD[b]

Chicago, Illinois

All 391 patients treated for gestational trophoblastic tumors (invasive mole and choriocarcinoma) at the John I. Brewer Trophoblastic Disease Center of Northwestern University between 1969 (when use of combination chemotherapy for initial treatment of high-risk disease came into general use) and 1988 were evaluated. Univariate and multivariate analyses were used to determine the relative importance of prognostic factors with respect to survival. The overall cure rate was 93% (363/391): 100% for 223 patients with nonmetastatic disease and 83% for 168 patients with metastatic disease. The only patients who died had a clinicopathologic diagnosis of metastatic choriocarcinoma. In addition to presence of metastasis (83% vs 100%, $p < 0.0001$) and diagnosis of choriocarcinoma (67% vs 100%, $p < 0.0001$), number of metastases (47% if >8 vs 92% if ≤8, $p < 0.0001$), metastases to sites other than the lung or vagina (52% vs 91%, $p = 0.0002$), and previous failed chemotherapy (46% vs 84%, $p = 0.0014$) demonstrated independent significant effects on survival in patients with metastatic disease. A Brewer score, based on our multivariate analysis of survival in patients with metastatic disease, provided predictability of outcome (likelihood ratio χ^2 statistic, $\chi^2 = 49.8$) comparable to that with the World Health Organization score ($\chi^2 = 45.3$), both of which, in turn, were better predictors than either the traditional Hammond clinical classification system ($\chi^2 = 34.4$) or the International Federation of Gynecology and Obstetrics stage ($\chi^2 = 22.9$). (Am J Obstet Gynecol 1991;164:611-6.)

Key words: Gestational trophoblastic disease, trophoblastic tumors, choriocarcinoma

Hertz et al.[1] and Ross et al.[2] first emphasized that the successful treatment of gestational trophoblastic tumors was dependent on four factors: (1) duration of disease before initiation of chemotherapy, (2) elevation of the pretreatment human chorionic gonadotropin (hCG) level, (3) absence of central nervous system or hepatic metastases, and (4) proper administration of chemotherapy. Hammond et al.[3] subsequently showed that most patients with metastatic disease and one or more of these high-risk factors could be cured by the use of initial multiple-agent rather than single-agent chemotherapy. This led to the clinical classification of gestational trophoblastic tumors into three groups: nonmetastatic, low-risk metastatic, and high-risk metastatic, where "high risk" referred to those patients who were not likely to be cured by single-agent methotrexate or actinomycin D chemotherapy.

Bagshawe[4] later proposed a prognostic scoring system based on various factors that were thought to influence prognosis. In 1983 the World Health Organization (WHO)[5] adopted a modification of this scoring system based on patient's age, type of antecedent pregnancy, time interval between antecedent pregnancy and trophoblastic tumor, hCG level, paternal and maternal blood type, number and site of metastases, largest tumor mass, and previous chemotherapy. A weighted score was applied to each factor, each was presumed to act as an independent variable, and their effects were assumed to be additive. Patients with scores of ≥8 were regarded as high risk for treatment failure.

An anatomic staging system, based on data presented by Sung et al.,[6] was adopted by the International Federation of Gynecology and Obstetrics (FIGO) Cancer Committee in 1982.[7] Stage I tumor is strictly confined to the uterine corpus, stage II extends outside the uterus but is limited to the genital structures, stage III tumor extends to the lungs with or without genital tract involvement, and stage IV tumor is metastatic to any other site(s).

Because of the wide variety of classification and scoring systems now used to group patients with gestational trophoblastic tumors for treatment purposes and because the identification of high-risk criteria has been based on univariate analysis, there is no agreement as to which system is best at predicting outcome and which prognostic factors are most important. It is the purpose of this report to use both univariate and multivariate

analysis of commonly used prognostic factors and other descriptive features to determine the relative importance of these factors and to compare the present classification systems with a proposed scoring system based on the multivariate analysis.

Material and methods

Between 1969 and 1988, 391 patients completed treatment for gestational trophoblastic tumors (invasive mole and choriocarcinoma) at the John I. Brewer Trophoblastic Disease Center of Northwestern University Medical School. All patients underwent investigative studies before treatment, including physical examination, chest roentgenography, liver-spleen scan, brain scan, blood chemistry and hematology profile, and hCG determination. In recent years computed tomography of the brain, abdomen, and pelvis has replaced other studies. After these initial studies 223 patients (57%) were categorized as having nonmetastatic disease and 168 patients (43%) were determined to have metastatic gestational trophoblastic tumors. Seventy-three (43%) of these 168 patients with metastatic disease were further classified as being at high-risk on the basis of presence of one or more of the following: (1) immediate pretreatment hCG level in excess of 100,000 mIU/ml or serum β-subunit assay >40,000 mIU/ml, (2) time >4 months from antecedent pregnancy or onset of symptoms to treatment, (3) metastases to sites other than the lungs and/or vagina, (4) antecedent term gestation, and (5) prior unsuccessful chemotherapy.

All 223 patients with nonmetastatic disease and most of the 95 patients with low-risk metastatic disease were treated primarily with single-agent methotrexate 0.4 mg/kg or occasionally actinomycin D 10 to 12 μg/kg intravenously daily for 5 days per course. Treatment courses were repeated as often as toxicity permitted, usually every 14 days. Beginning in 1969 patients with high-risk metastatic gestational trophoblastic tumors were treated primarily with combination chemotherapy. Before 1981 the standard combination regimen used was MAC, consisting of methotrexate 15 mg, actinomycin D 0.5 mg, and cyclophosphamide 3 mg/kg (maximum 200 mg), all given intravenously daily for five consecutive days. Courses were usually repeated every 14 days, depending on hematologic recovery and toxicity. In 1981, the seven-drug modified Bagshawe protocol CHAMOCA, consisting of hydroxyurea, actinomycin D, methotrexate with folinic acid rescue, cyclophosphamide, vincristine (Oncovin), and doxorubicin (Adriamycin), replaced the MAC regimen for primary treatment of high-risk patients. After 1984 all high-risk patients were treated with the EMA-CO regimen, which included etoposide, high-dose methotrexate with folinic acid rescue, actinomycin D, cyclophosphamide, and vincristine. There were no significant differences in response with respect to chemotherapy regimen, although all patients treated after 1981 survived. Cerebral metastases were treated simultaneously with a single course of whole-organ irradiation of 3000 to 4000 cGy. Adjuvant surgical procedures, including hysterectomy and thoracotomy for excision of resistant foci of tumor, and/or irradiation of metastases at sites other than the brain were performed in selected patients.

Response to treatment was determined by hCG assays, change in size or disappearance of existing metastases, or appearance of new lesions. Chemotherapy was changed if the hCG level plateaued or rose after two chemotherapy courses or if toxicity precluded an adequate dose or frequency of treatment. Patients not responding to single-agent chemotherapy were most often treated with MAC. Patients who developed progressive disease on the MAC or CHAMOCA regimens were treated with other agents or combinations of agents including etoposide, bleomycin, and cisplatin.

During treatment, patients were monitored by physical examinations and hematology and chemistry profiles. Studies with prior abnormal results were repeated at appropriate intervals. Serum for hCG determination was obtained immediately before each treatment course. Radioimmunoassays for hCG were done from 1968 on and additionally for the β-subunit of hCG starting in 1972. Normal ranges for hCG with these assays were <20 and <2 mIU/ml, respectively. Complete remission was diagnosed after three consecutive weekly hCG levels were within normal range. At least two additional courses of chemotherapy were given after the first normal hCG level. After remission, hCG levels were obtained monthly for 6 months, every other month for the remainder of the first year, every 3 months during the second year, and at 6-month intervals indefinitely thereafter. Patients were advised not to become pregnant for 1 year after the completion of chemotherapy.

The clinical records maintained on all patients in the administrative office of the Brewer Trophoblastic Disease Center were reviewed to determine the patient's age, antecedent pregnancy, pretreatment hCG level, duration of disease, pathologic diagnosis if known, sites, size, and number of metastases, type of chemotherapy, including previous failed chemotherapy, and outcome with length of follow-up or date of death. Patients were also retrospectively assigned to FIGO stage and given a score according to a modification of the WHO prognostic scoring system (omitting ABO blood groups).

Statistical analysis of the univariate association between prognostic factors and survival was done with the log rank test. Multivariate analysis of survival time was by Cox regression analysis. Multivariate analyses were compared descriptively with a log likelihood ratio χ^2 statistic and 1 *df*. The χ^2 statistic was used as a mea-

sure of the prognostic ability of the model. Hazard ratios were used to compare across categories of a prognostic factor.

Results

The overall cure rate was 93% (363/391): 100% for 223 patients with nonmetastatic disease and 83% for 168 patients with metastatic disease. Univariate analysis was used to determine the relative effect of various prognostic factors on survival in the 168 patients with metastatic disease (Table I).

Patients with metastatic disease ranged in age from 14 to 53 years with a median age of 25 years. Fifteen patients (8.9%) were ≥40 years old. There was no effect of age on survival. The survival rate was 83% for patients <40 years old compared with 87% for patients ≥40 years old.

Pretreatment hCG values ranged from 5 to 10,000,000 mIU/ml with a median of 5000 and a mean of 18,750. Forty-eight patients (28.6%) had hCG levels >100,000 mIU/ml at the initiation of treatment. In univariate analysis hCG level had a significant effect on survival. Survival was 87% for patients with hCG values <100,000 versus 75% for patients with hCG levels ≥100,000 ($p = 0.05$).

Similarly, duration of disease had a significant effect on survival. Time from antecedent pregnancy to treatment ranged from 0 to 136 months with a mean of 6.5 months and a median of 2 months. Twenty-five percent of patients had a duration of disease >4 months. The survival rate was 90% for patients with a short duration of disease versus 64% for patients who were treated >4 months from the antecedent pregnancy ($p = 0.0003$).

The types of pregnancies associated with the development of metastatic trophoblastic tumors were: hydatidiform mole in 110 (65.5%), abortion in 29 (17.3%), ectopic in 1 (0.6%), and term in 28 (16.7%). Antecedent pregnancy had a very significant effect on survival in patients with metastatic disease ($p = 0.001$). The survival rate was 91% in patients with a preceding hydatidiform mole compared with 69% in patients with a nonmolar gestation.

Metastasis had a profound effect on survival. All 223 patients with nonmetastatic disease survived. If metastatic disease was confined to the lung and/or vagina, the survival rate was 91% (123/135) versus 52% (17/33) in patients with metastases at other sites ($p < 0.0001$). Similarly, if more than one metastatic site was involved, survival decreased from 91% (121/133) to 54% (19/35) ($p < 0.0001$). As the number of individual metastases increased, the survival rate decreased from 96% (87/91) for one to four metastases, to 84% (38/45) for five to eight metastases, to 47% (15/32) for more than eight metastases ($p < 0.0001$).

Size of the largest tumor (including uterine tumor) had a significant effect on survival in patients with metastatic disease. Tumor size was <3 cm in 114 patients, 3 to 5 cm in 33 patients, and >5 cm in 21 patients. The survival rate was 92% for patients with tumors <3 cm, versus 73% for patients with tumors 3 to 5 cm, versus 52% for patients with tumors >5 cm ($p < 0.0001$).

A clinicopathologic diagnosis of metastatic choriocarcinoma was made in 86 patients on the basis of histopathologic examination of a sufficient number of tissue specimens showing hyperplastic and dysplastic trophoblast without formed stromal villi or development of trophoblastic tumor in association with a nonmolar pregnancy. Invasive mole was diagnosed histologically in 20 patients, whereas no pathologic diagnosis could be made in 62 patients who were treated without a histologic diagnosis after evacuation of a hydatidiform mole because of plateaued or rising hCG levels with or without demonstration of metastases. All patients who died had a clinicopathologic diagnosis of metastatic choriocarcinoma. The survival rate for patients with metastatic choriocarcinoma was 67% (58/86) versus

†Clinicopathologic diagnosis of choriocarcinoma excluded from model because all patients who died had metastatic choriocarcinoma.

‡Estimated increase in risk of death per unit change in variable category.

100% for 82 patients with presumed metastatic invasive mole ($p < 0.0001$).

Eleven patients with metastatic disease had received chemotherapy before referral to our center for further therapy. Only 5 (46%) of these patients were cured compared with 135 of 157 (86%) patients who were treated primarily at our center ($p = 0.0005$).

When multivariate analysis was carried out for survival, both presence of metastases and clinicopathologic diagnosis of choriocarcinoma were excluded from analysis, because only patients with metastatic choriocarcinoma died. Multivariate analysis was performed for the 168 patients with metastatic disease, the 86 patients with metastatic choriocarcinoma, and the 73 patients with traditional high-risk metastatic disease treated with multiagent chemotherapy. Number of metastases, metastases to sites other than the lung and/or vagina, and previous failed chemotherapy demonstrated independent significant effects on survival in all groups analyzed (Table II).

A comparison of the FIGO staging system, the WHO score, the traditional Hammond clinical classification, and our multivariate analysis in predicting outcome was carried out. All patients with FIGO stage I trophoblastic tumors (223) were cured. The only patient with stage II disease who died (1/10) had a large pelvic tumor complicated by hemorrhage and anemia; the WHO score was 8 and the hCG level was normal at death. Thirteen (10%) of 133 patients with stage III disease died: one with a WHO score of 6 who relapsed with brain metastases and 12 with scores of ≥8 (mean = 11). Fourteen (56%) of the 25 patients with stage IV disease died, all but two of whom had WHO scores of ≥11 (mean = 14). Two patients who died, with scores of 7 and 9, had brain and gastrointestinal metastases, respectively. There was a significant difference in survival rates between stage IV (44%) and stages II and III (90%) ($p < 0.0001$).

According to the traditional nonmetastatic and metastatic low-risk and high-risk disease classifications, 168 patients with metastatic disease were categorized into low-risk ($n = 95$) and high-risk ($n = 73$) groups. Ninety-three patients with low-risk metastatic disease (98%) and 47 high-risk patients (64%) achieved complete remission ($p < 0.0005$). The only two deaths in the low-risk group occurred in patients with WHO scores of ≥8. Among the 73 high-risk patients, 21 of 23 (91%) with a WHO score of <8 attained remission compared with 26 of 50 (52%) with scores of ≥8 ($p = 0.003$).

Modified WHO prognostic scores for the 168 patients with metastatic disease ranged from 1 to 20 with a mean of 6.3. Survival rates were 100% for 79 patients with scores ≤4, 94% for 33 patients with scores 5 to 7, and 54% for 56 patients with scores ≥8 ($p < 0.0001$).

These three classification systems were compared with a simplified prognostic scoring system (Brewer score) that is based on our multivariate analysis in metastatic cases by use of the likelihood ratio χ^2 statistic. The Brewer score was derived by assigning component scores from 0 to 3 on the basis of weights of the three significant variables from the multivariate analysis of survival. Points were assigned as follows: 0 for lung and/or vaginal metastases and no prior chemotherapy, 1 for one to four metastases, metastases other than lung and/or vaginal metastases, and prior chemotherapy, 2 for five to eight metastases, and 3 for more than eight metastases. The total score was the sum of the components. Survival in the 168 patients with metastatic disease with respect to this Brewer score was 100% (79/79) with a score of 1, 88% (37/42) with a score of 2, 63% (19/30) with a score of 3, and 29% (5/17) with a score of 4. The Brewer score had the largest χ^2 (49.8), indicating that it was the strongest of the predictors of survival outcome as compared with the WHO score ($\chi^2 = 45.3$), the traditional Hammond clinical classification system ($\chi^2 = 34.4$), and the FIGO stage ($\chi^2 = 22.9$). All four classification or scoring systems provided significant predictability of outcome ($p < 0.0001$).

Comment

After the initial reports of success of chemotherapy in the treatment of gestational trophoblastic tumors, it became apparent that certain patients with metastatic disease were more likely to fail therapy. By 1965, investigators at the National Cancer Institute had described several prognostic factors that identified a

group of patients with metastatic tumors who were likely to develop resistance to single-agent chemotherapy.[1,2] Hammond et al.[3] later showed that most of these patients with high-risk metastatic disease could be cured with initial multiple-agent chemotherapy. Additional prognostic factors were later proposed by Bagshawe[4] and Sung et al.[6] and are the basis of the WHO prognostic scoring system[5] and the FIGO staging system,[7] respectively.

The overall cure rate in the treatment of gestational trophoblastic tumors now exceeds 90%. In this study 363 of 391 patients (93%) were cured, including all 223 patients with nonmetastatic disease and 140 of 168 patients (83%) with metastatic disease. Virtually the only patients who die have high-risk metastatic choriocarcinoma when they are initially seen. Intensive therapy with combination chemotherapy and, where indicated, adjuvant radiotherapy and surgery has resulted in cure rates of 80% to 90% in this group of patients. On the basis of our analysis the prognostic factors that are most important in determining response to treatment in these high-risk patients are: (1) clinicopathologic diagnosis of choriocarcinoma, (2) metastases to sites other than the lung or vagina, (3) number of metastases, (4) previous failed chemotherapy, and (5) WHO prognostic score of ≥8 or Brewer score of 3 or 4.

The only patients who have died of trophoblastic tumor at the Brewer Center have had either histologically verified metastatic choriocarcinoma and/or tumor developing in association with a nonmolar gestation.[9-10] Of 391 patients treated between 1969 and 1988, all 82 patients with a clinicopathologic diagnosis of metastatic invasive mole survived, whereas survival in the 86 patients with metastatic choriocarcinoma was 67% ($p < 0.0001$). Goldstein,[11] Soper et al.,[12] and Azab et al.[13] have also reported a significantly poorer prognosis in patients with a clinicopathologic diagnosis of choriocarcinoma.

The site of metastasis is known to have a profound effect on survival.[1,2,4,8,13-16] At the Brewer Center, when metastatic disease was confined to the lung and/or vagina, survival was 91% (123/135) versus 52% (17/33) when other metastatic disease was present at initiation of treatment ($p < 0.0001$). Approximately half (8/15) of the patients with brain metastases and two thirds (6/9) of the patients who presented to the center with liver and/or intraperitoneal metastases died.

Additionally the number of metastases significantly affects survival. Bagshawe[4] first noted this as an important prognostic factor and incorporated this into the scoring system that was subsequently adopted by the WHO.[5] Survival decreased from 96% for patients with one to four metastases, to 84% for patients with five to eight metastases, to 47% for patients with more than eight metastases ($p < 0.0001$). Number of metastases ($p < 0.0001$) and metastatic site ($p = 0.0002$) were the two most significant factors affecting survival on multivariate analysis.

Number of metastatic sites was an important prognostic factor in univariate analysis. Survival was 91% in 133 patients with metastases to only one anatomic site compared with 54% in 35 patients with more than one site of metastatic involvement ($p < 0.0001$). In multivariate analysis, however, number of metastatic sites did not quite achieve statistical significance to be entered into the model. Soper et al.[12] and Azab et al.[13] reported a significantly decreased survival with metastatic involvement at more than one site, and the latter group found that initial presentation with metastases to more than one organ significantly affected survival on multivariate analysis (relative risk = 7.4, $p < 0.01$).

Secondary treatment of patients with gestational trophoblastic tumors yields poor results.[2,3,8,11,13-17] We previously reported that the cure rate was only 30% in 27 high-risk patients who were transferred to the Brewer Center after failure of treatment elsewhere, as compared with 63% for 46 high-risk patients treated initially with MAC at the center between 1968 and 1982 ($p < 0.01$).[14] In this report only 5 of 11 patients (46%) who had failed prior chemotherapy for metastatic disease were cured, compared with 135 of 157 patients (86%) with metastatic disease who were treated primarily at our center ($p = 0.0005$). In both this report and that of Azab et al.[13] prior unsuccessful chemotherapy exhibited a significant independent adverse effect on survival in multivariate analysis.

Other traditional high-risk factors such as hCG level, duration of disease, and antecedent pregnancy have less effect on response to treatment in high-risk patients treated with initial, appropriate multiagent chemotherapy.[4,12-17] Although these factors were significantly associated with survival in univariate analysis in our series, they did not enter into the multivariate model for survival. These factors, however, seem to have an additive effect with other, more important prognostic variables. At the Brewer Center, if one or two high-risk factors were present, survival was 74% compared with 27% in patients with three or more high-risk factors ($p < 0.005$).[14] Bagshawe,[4] Soper et al.,[12] and DuBeshter et al.[17] also observed an additive effect of these factors.

The WHO score seems to be a very important predictor of treatment outcome.[4,5,16-19] Of 28 patients who died of trophoblastic tumors at the Brewer Center between 1969 and 1988, 93% had a WHO score ≥8 (high-risk group). The average score was 13 (range 6 to 20). Ninety-one percent of traditional high-risk patients with scores of <8 were cured, compared with 52% of patients with scores of ≥8 ($p < 0.003$). The Brewer

score derived from our multivariate analysis, as outlined in this report, was also a strong predictor of survival outcome in patients with metastatic disease ($p < 0.0001$). All patients with a score of 1 were cured, compared with 88% of patients with a score of 2, 63% of patients with a score of 3, and 29% of patients with a score of 4. The simpler Brewer score ($\chi^2 = 49.8$) was comparable to the WHO score ($\chi^2 = 45.3$) in predicting survival outcome.

Transient postpartum diabetes insipidus

A. Raziel, MD,[a] T. Rosenberg, MD,[b] P. Schreyer, MD,[a] E. Caspi, MD,[a] and Y. Gilboa, MD[b]
Tel Aviv, Israel

Diabetes insipidus may first present before, during, or immediately after pregnancy. The characteristics of two unusual cases of transient postpartum diabetes insipidus are described and discussed. (AM J OBSTET GYNECOL 1991;164:616-8.)

Key words: Diabetes insipidus in pregnancy, diabetes insipidus in puerperium, transient diabetes insipidus

From the Departments of Obstetrics and Gynecology[a] and Endocrinology,[b] Assaf Harofeh Medical Center, affiliated with Sackler School of Medicine, Tel Aviv University.

6/1/24742

The coexistence of diabetes insipidus with pregnancy appears to be rare.[1] Diabetes insipidus that occurs before or during pregnancy is frequently influenced by gestation and persists for years post partum.[2] Transient diabetes insipidus is a variant of disease that occurs in pregnancy and resolves spontaneously after delivery;

it was formerly called diabetes insipidus gravidarum.[3] Pregnancy serves as a provocation test that unmasks possible latent diabetes insipidus; thus, the existence of diabetes insipidus that first appears after a normal delivery is highly unusual.

We describe two rare cases of postpartum transient diabetes insipidus that occurred in the *immediate puerperium only*, after non-traumatic cesarean sections with rapid amelioration and no recurrences in other pregnancies.

Case reports

Case 1. A 23-year-old primigravida woman complained of polyuria and polydipsia on the first day after cesarean section, which was performed with the patient under spinal block with tetracaine 12 mg, at 42 weeks' gestation, because of cephalopelvic disproportion. No decrease in blood pressure was noted. Intramuscular erythromycin was administered as prophylaxis. In the past she had no significant illness, and the recent course of pregnancy was uneventful. On the first postoperative day a marked polyuria and polydipsia was noted with a urine volume of approximately 11 L/day and fluid intake of 6.2 L/day. The results of plasma biochemistry tests were sodium level 159 mEq/L, hematocrit 40%, creatinine level 1.4 mg/dl, blood osmolality 321 mOsm/kg, and urine osmolality 42 mOsm/kg. In addition to fluids, large amounts of 5% glucose were administered to prevent dehydration and hypernatremia. Intravenous administration of 1 U vasopressin induced a strong antidiuresis; therefore on the third postoperative day nasal administration of two doses of 100 μl of 1-deamino-8-D-arginine vasopressin was started and reduced the high urine volume. Urine osmolality rose to 470 mOsm/kg, and blood osmolality returned to normal, 285 mOsm/kg. The prominent response to 1-deamino-8-D-arginine vasopressin is detailed in Table I.

In a search for the cause of postpartum diabetes insipidus, chest x-ray film, skull computed tomography, and visual fields were performed and found to be normal. The woman left the hospital with no complaints of polyuria and polydipsia on the tenth postoperative day and without any treatment. Three months after delivery there were no complaints and a good urinary concentration after overnight fast. One year and three years after this episode of transient postpartum diabetes insipidus, the woman underwent repeated cesarean sections in our hospital, at term while she was under epidural anesthesia with no evidence of water metabolism disturbances.

Case 2. A 36-year-old woman, gravida 3, para 2, noticed intense thirst 8 days after cesarean section. All three pregnancies had been achieved after induction of ovulation with human menopausal gonadotropins. The last two pregnancies were complicated by White's class B diabetes mellitus. A bleeding placenta previa, at 20 weeks' gestation, was the indication for hysterotomy of the first pregnancy. The second and third pregnancies ended at term by low-segment transverse cesarean sections. The last cesarean section was performed with the patient under epidural anesthesia with 2% lidocaine. Blood pressure between 120/70 and 130/70 mm Hg was measured several times during the operation. The week after the operation was uneventful. On the eighth postoperative day, a spiking fever of 38.6° C that lasted for only 24 hours was followed by polyuria and polydipsia. Fluid intake of about 4 L/day and urine volume that reached 6.2 L/day were noted, and there was no response to 5.0 IU vasopressin given subcutaneously and to gradual increase of nasal 1-deamino-8-D-arginine vasopressin up to 100 μl three times a day. On the eighteenth day of hospitalization, in view of the lack of effect of 1-deamino-8-D-arginine vasopressin, the medication was stopped. Frequent water deprivation tests were performed during the 3 months after the operation, while the patient was receiving no treatment. A gradual return to normal diuresis and drinking was observed, with similar normal changes in the osmolality of blood and urine as shown in Table II.

Comment

The exact incidence of diabetes insipidus appears to be two to four cases in 100,000 pregnancies, which is similar to the prevalence of diabetes insipidus in nonpregnant patients. The connection between pregnancy and diabetes insipidus is divided into three main categories: (1) pregnancy in patients with preexisting diabetes insipidus, (2) diabetes insipidus that occurs during pregnancy (including the transient form, "diabetes insipidus gravidarum"), and (3) diabetes insipidus that occurs immediately after delivery.

Pregnancy serves as a physiologic provocation test that unmasks latent diabetes insipidus. This may explain the very rare first occurrence of diabetes insipidus in the puerperium.

Among diabetes insipidus that first occurs during pregnancy there is a transient form that ameliorates after delivery. Three transient types, central type (antidiuretic hormone-responsive), nephrogenic type (antidiuretic hormone-resistant), and responsive type (antidiuretic hormone-resistant 1-deamino-8-D-arginine vasopressin-responsive), have been reported.[2]

Our two cases represent a transient form of diabetes insipidus that occurs after delivery by cesarean section; one patient was sensitive to 1-deamino-8-D-arginine vasopressin and the other was insensitive to 1-deamino-8-D-arginine vasopressin and vasopressin. The first patient returned to normal very soon after a good response to 1-deamino-8-D-arginine vasopressin that was administered nasally, and the second patient, although unresponsive to any form of antidiuretic hormone, also returned to normal during a period of 3 months.

During pregnancy there is a gradual increase in the metabolic clearance of arginine vasopressin and in placental vasopressinase activity. Levels of vasopressinase decrease at a logarithmic rate of 25%/day and become undetectable a month after delivery. Delayed decrease in vasopressinase, exaggerated metabolic clearance of arginine vasopressin, or any kind of resistance of the kidney to arginine vasopressin may cause this transient form of diabetes insipidus.

In both cases marked polyuria and polydipsia developed after cesarean section with no anesthetic complications. There was no indication that diabetes insipidus was a complication of anesthesia because both women had two cesarean sections, one of them after and the other before the occurrence of transient diabetes insipidus, and neither woman had a recurrence of diabetes insipidus.

Postterm infants: Too big or too small?

Frances H. McLean, BScN, Mark E. Boyd, MD, Robert H. Usher, MD, and Michael S. Kramer, MD*

Montreal, Quebec, Canada

Concern over the postterm pregnancy has shifted from that of the difficult delivery of an excessively large fetus to the current concern with death in utero of an undernourished, small-for-date fetus. Studies of postterm pregnancy before the availability of ultrasonography may have included a large proportion of erroneous menstrual dates. The present study of 7000 infants was undertaken to reassess fetal growth in postterm pregnancies in which the expected date of confinement from last normal menstrual period dating was confirmed (±7 days) by early ultrasonography. Results show a gradual shift toward higher birth weight and greater crown-heel length and head circumference between 273 and 300 days of gestational age. No evidence of postterm weight loss or lower weight for length could be demonstrated. Concern in postterm pregnancy should be for fetal macrosomia, not for intrauterine growth retardation. (AM J OBSTET GYNECOL 1991;164:619-24.)

Key words: Fetal growth, postterm

The controversy as to whether postterm infants tend to be "too big" or "too small" remains unresolved. In 1902, Ballantyne described the postterm infant as excessive in size and the essential problem with delivery as cephalopelvic disproportion.[1] There have since been several studies that reported increased rates of macrosomic infants in pregnancies that progressed past term.[2-6] In contrast, Clifford[7] described the long, thin postterm infant with "the picture of recent weight loss" that he attributed to placental dysfunction, which led to fetal wasting, hypoxia, meconium release, and death. Since this description, there have been additional reports of this "placental dysfunction syndrome." The current concern of the postterm pregnancy usually relates more to fetal jeopardy from deprivation of oxygen and nutrition than to difficult delivery.

The conflicting opinions about the size of the postterm infant, the need for increased surveillance before labor, and the induction of labor have been discussed in the literature but with differing conclusions.[8,9] There appears to be no doubt that the "placental dysfunction syndrome" can occur, but there is no evidence that it occurs only or even more frequently in postterm pregnancies than it does at or before term.

One problem involves determining which infants are actually postterm. Previous studies considered infants to be postterm on the basis of the expected date of confinement calculated from the mother's last normal menstrual period. It has recently been shown that in only a small minority of infants considered postterm by last normal menstrual period could the menstrual age be confirmed by early ultrasonography.[10,11]

Another possibility is that the postterm population may include both types of infants (some too big and others too small or too scrawny); if so, population distribution by birth weight must be analyzed and not determined from mean values.

The present analysis of fetal growth characteristics and body proportions was therefore undertaken on a population in whom gestational age from last normal menstrual period was confirmed to within 7 days by early ultrasonography. Confirmed "postterm" infants (≥42 completed weeks) are compared with those born at 39, 40, and 41 weeks from the onset of the last normal menstrual period.

Population and methods

The infants studied were delivered between Jan. 1, 1978, and March 31, 1986, at the Royal Victoria Hospital, Montreal, and were previously reported with respect to obstetric management and fetal outcome.[10,12] Criteria for inclusion in the study were known date of onset of the last normal menstrual period, early (usually 16 to 18 weeks) ultrasonography measurement from which an estimated date of confinement was entered into the McGill Obstetric and Neonatal Database,[13] concordance (±7 days) of the estimated date of confinement on the basis of menstrual history and early ultrasonography, and delivery at or after 39 weeks (273 days) from onset of the last normal menstrual period.

Of the 7663 infants who met these criteria, 7005 were included in this study after the exclusion of pregnancies with conditions known to disturb fetal growth (multiple births, maternal hypertension or diabetes, fetal Rh erythroblastosis, hydrops fetalis, major malformations, and TORCH [toxoplasmosis, rubella, cytomegalovirus, herpes] infections).

Infants were weighed to the nearest 5 gm on a balance scale in the nursery within an hour after delivery. Placentas with cord and membranes attached were weighed immediately after birth in the delivery room on similar scales.

Crown-heel length and head circumference were measured during the routine admission examination. These measurements have been recorded in the McGill Obstetric and Neonatal Database since 1981, and are therefore available for only 4020 of the infants.

Weight-for-length (as a measure of nutritional status) was assessed by ponderal index (birth weight in grams multiplied by 100 and divided by the cube of length in centimeters). A ponderal index of 2.2 was considered to be the lower limit of normal because this level was the 3rd percentile in a series of consecutively born infants at ≥37 weeks, as reported by Miller and Hassanein.[14]

"Severe intrauterine growth retardation" was defined as a birth weight at least 25% below the mean weight for gestational age as calculated from the infants in this study population. As indicated in a prevoius report, this definition corresponds to the 1.7th percentile for our hospital population.[15]

Growth and body proportions were compared for infants delivered within four completed 1-week periods from 39 to 42 6/7 weeks. Only five infants were delivered at 43 weeks or later; this number was too small to be included in the analysis.

The data for each week were analyzed separately for primiparous women and multiparous women, because the impaired growth has been described to occur predominantly in primiparous patients,[7] because postterm pregnancies in our population occur more frequently in primiparous women, and because infants born to primparous patients are smaller than those of multiparous patients.[10]

Statistical analyses were conducted with Statistical Analysis Systems methods.[16] Linear trends in means were tested (F test for linear trend, F_L) with the general linear models procedure. Analyses for proportions were based on Mantel-Haenszel χ^2 tests for linear trend (χ^2_L).

Results

In the infants of both primparous and multiparous women, mean birth weight increased from 39 through 42 completed weeks (Table I). Infants born to multiparous women had a consistently higher mean weight than did those born to primiparous women. A similar increase with advancing gestational age was seen for mean crown-heel length and head circumference (Table II). Infants whose length and head circumference measurements were available had mean birth weights at each gestational age that were almost identical to the birth weights of infants in the group as a whole.

The distribution of birth weights in 500 gm intervals shows a pronounced shift toward higher birth weight categories with advancing gestational age in the infants of both primiparous and multiparous women (Fig. 1). Considering all infants in the study, without regard to parity, there were no low-birth-weight (<2500 gm) infants by 42 weeks, but there was a marked increase in large (≥4000 gm) infants (9% at 39 weeks, 15% at 40 weeks, 22% at 41 weeks, and 30% at 42 weeks). Macrosomia was particularly a problem among the postterm infants (42 weeks) of multiparous women, 43% of whose infants weighed at least 4000 gm.

To determine if there was a tendency toward a bimodal distribution of birth weights (some infants were growth-retarded and others were excessively large), the distribution by 100 gm intervals was also analyzed for infants born at 39 to 40 weeks (273 to 286 days) as compared with those born at 41 weeks (287 to 293 days) and at 42 weeks (294 to 300 days). The distributions had virtually identical shapes; no evidence of bimodality was found after term (Fig. 2). Coupled with the

fact that the coefficient of variation (standard deviation/mean) for birth weight does not increase as gestational age progresses (Table I), these data suggest no tendency for some infants to lose weight while others continue to grow after term.

There was no tendency in either primparous women or multiparous women for severe intrauterine growth retardation to occur more frequently after term than at term (Table III). Only two of the 84 infants with severe intrauterine growth retardation were delivered after term (42 weeks).

Ponderal index at different gestational ages was also analyzed to determine if there was any evidence of intrauterine weight loss after term. None could be demonstrated, inasmuch as the mean ponderal index and the proportion of infants with low ponderal index show

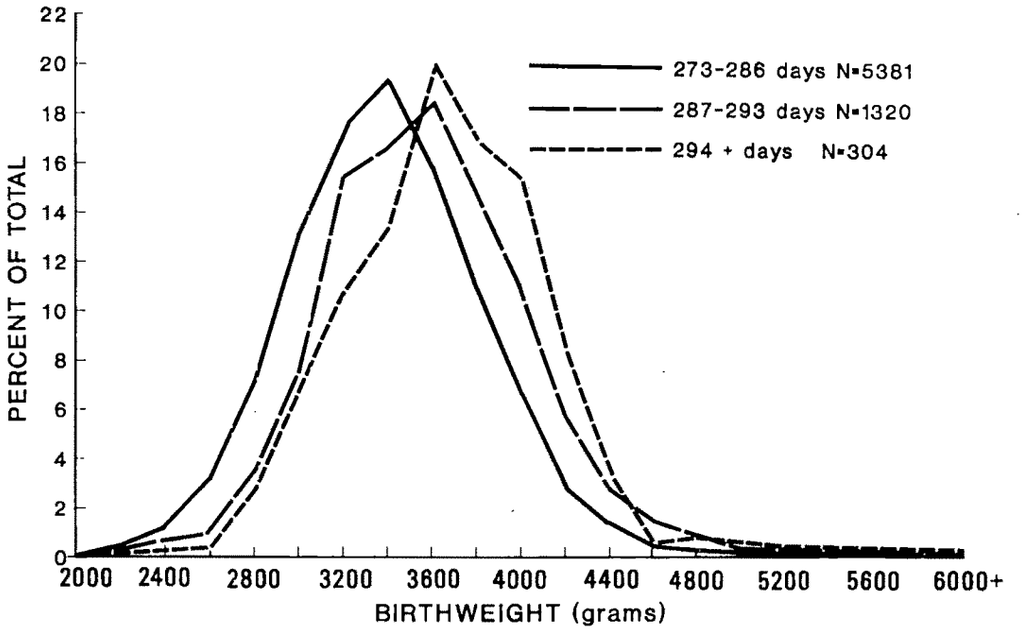

Fig. 2. Distribution of birth weight by 100 gm intervals for infants of different gestational ages.

no tendency toward decreasing weight-for-length as pregnancy progressed after term; in fact, for the infants of primiparous women, the data indicate just the opposite (Table IV).

Placental weight increased as pregnancy progressed, as did infants' birth weight. Ratios of fetal weight to placental weight were constant at all gestational ages studied (Table V). There was no evidence of absolute or relative reduction in placental weight after term.

Comment

In the early years of this century, apprehension with respect to postterm pregnancy was related to the difficulty of delivery in cases of an excessively large fetus. More recently, this concern has been replaced by concern for a growth-retarded, undernourished fetus at risk of morbidity or mortality from hypoxia; this has led to an emphasis on close surveillance of postterm gestations for fetal size and well-being. However, there is a lack of convincing evidence that the postterm fetus is at increased risk of distress or nutritional deprivation. It has been the purpose of this study to determine how frequently either macrosomia (≥4000 gm) or intrauterine growth retardation develops in infants who remain in utero after term, when the "postterm" status by last normal menstrual period has been confirmed by a more reliable method.

Gestational age has been customarily calculated from the last normal menstrual period. The potential sources of error in this method are well known, although the magnitude and direction of these errors have only more recently been described.[11, 17] As measured by early ul-

Fetal-placental ratio is the ratio of fetal weight to placental weight.

trasonography, the overall validity of last normal menstrual period dating for an infant born at term by last normal menstrual period is 95%, whereas the probability that an infant considered to be born after term, as based on the mother's last normal menstrual period, actually was postterm is only 12%.[11] Studies of postterm pregnancies with last normal menstrual period alone used for determining gestational age include many pregnancies with erroneous dates.

There is also an inconsistency in the definition of "postterm." Different authors consider a postterm infant to be one delivered at or after 41 weeks[6, 8] or, more frequently, at 42 weeks[3, 9, 10] or even at 43 weeks.[2, 4, 7] This issue is further confused by varying interpretations of terminology. Deliveries assigned to a certain week may have occurred during that week or after that week has been completed, or they may be of uncertain date. Gestational age in completed weeks in the present study is unambiguously defined by stating the days included.

The publication that led to the concept that infants may become undernourished if they remain in utero after term was Clifford's description[7] of the "postmaturity syndrome," which is based on 37 infants selected by clinical features who were delivered from 3 to 44 days after term. The relative risk of development of these features after term was not studied, nor was a comparison of birth weights made with controls.

After this study, Sjostedt et al.[18] classified 1171 infants as normal or abnormal on the basis of clinical inspection of the infant according to Clifford's classification but without prior knowledge of the duration of pregnancy. The mean weight of infants born between 39 and 44 weeks with signs of "postmaturity syndrome" was 200 gm less than the mean weight of "normal" infants of the same gestational age. Since the syndrome appeared to be present in some infants delivered before term, Sjostedt et al. renamed it "dysmaturity." Infants with and without signs of dysmaturity showed a similar weekly increase in birth weight from 39 to 43 weeks, but dysmature infants weighed less than the normal infants did at each week. It was concluded that although dysmaturity may be diagnosed after term, it is not caused uniquely by postterm delivery, since it can also be found before term. During the intervening 30 years since the publications by Clifford and Sjostedt et al., no published evidence was found that infants remaining in utero after term tend to become undernourished, although this concept has continued to receive wide acceptance.

However, reports of macrosomia in postterm pregnancies continue to appear.[1-6] The most recent such report was a study of 317 pregnancies with last normal menstrual period date confirmed by ultrasonography before 20 weeks. These patients were delivered of infants at 41 or 42 completed weeks.[6] Mean birth weight,

standard deviation, and frequency of infant birth weight >4000 gm in that study were similar to those found in the study cited here. Population distribution by birth weight and body measurements (and therefore ratios) of weight-for-length were not reported in this, only other study in which postdatism was confirmed by early ultrasonography.

Characteristic of all published fetal growth curves, including that from this institution,[19] is the decreased rate of growth starting about 36 or 37 weeks and a growth plateau at about 41 weeks that is followed by a subsequent decrease in mean birth weight. These curves are all based on menstrual history alone and are therefore distorted by errors in gestational age assignment in postterm deliveries.

The effect of such errors is demonstrable from the patient population in the present cohort that were excluded from analysis because early ultrasonographic dating assignments did not concur with the last normal menstrual period. The mean birth weight of all infants in this study whose mothers' menstrual dates were confirmed by early ultrasonography was 3482 gm if the infant was delivered at term (39 or 40 weeks) and 3735 gm if the infant was delivered after term (≥42 weeks). In contrast, the mean birth weight of all infants delivered after term according to a last normal menstrual period that could not be confirmed (early ultrasonography date >14 days different than last normal menstrual period date) was 3490 gm, which is very close to that of term infants in the study. Because a large majority of postterm dates are inaccurate, the overall mean in previous studies must have been markedly depressed by the inclusion of infants without confirmed dates.

Induction of labor around term, if selectively performed for growth-retarded infants, may have produced an artifactually large postterm birth weight. When the birth weight of the 18% of infants born after induction of labor between 273 and 286 days was analyzed, however, it failed to show that the induced labors produced smaller infants. Mean values within this gestational interval were 3506 gm among the infants delivered after induction of labor, as compared with 3470 gm after spontaneous labor.

When erroneous menstrual dates are eliminated with the use of early ultrasonography, mothers who are delivered of their infants after term produce large (not small) babies. Both fetal growth and placental growth continue after term. There is no evidence that infants experience growth failure or reduction in weight-for-length when pregnancy continues after term with any greater frequency than do infants delivered at term. Macrosomia, not intrauterine growth retardation, appears to be the valid concern in postterm pregnancy.

The biologic and social consequences of perinatal cocaine use in an inner-city population: Results of an anonymous cross-sectional study

Sandra McCalla, MD,[a] Howard L. Minkoff, MD,[a] Joseph Feldman, PhD,[b] Isaac Delke, MD,[a] Martin Salwin, MD,[c] Gloria Valencia, MD,[d] and Leonard Glass, MD[d]

Brooklyn, New York

Cocaine use among pregnant women and reports of its adverse perinatal consequences have increased substantially over the past 10 years. However, most researchers have studied patients registered at drug treatment centers or have relied on voluntary participation by patients, either of which introduces the possibility of selection bias. To determine the frequency and consequences of prenatal cocaine use among an unselected inner-city obstetric population, we collected urine samples from parturient women at a municipal hospital and anonymously tested these specimens for metabolites of cocaine, marijuana, opiates, and methadone. Urine specimens, with linked obstetric data sheets, were available from a study population of 1111 patients, and pediatric data sheets were available for 846 mother-infant pairs. Cocaine metabolites were found in 11.5% of the urine samples collected, whereas metabolites of marijuana, opiates, and methadone, respectively, were present in 1.1%, 1.2%, and 0.3% of the specimens. Cocaine users were more likely than nonusers to have had no prenatal care (51% vs 8.8%; $p < 0.0001$), to be American-born rather than Caribbean-born (71% vs 33%; $p < 0.001$), and to have a higher parity (1.83 vs 1.14; $p < 0.0001$). Infants of cocaine users had a lower mean gestational age (−0.93 weeks; $p < 0.01$), a lower mean birth weight (2560 ± 788 vs 3151 ± 699 gm; $p < 0.001$), and an increased probability of having an Apgar score of <7 at 5 minutes (12.5% vs 3.2%; $p < 0.0001$). Multiple linear regression analysis that isolated confounding variables such as the presence or absence of prenatal care, maternal age and parity, and the use of cigarettes and alcohol did not substantially affect the differences described above. The effect of cigarette smoking on reducing fetal size was cumulative. In conclusion, cocaine is the most commonly used illicit drug among parturients in this community and is strongly associated with underutilization of prenatal care services. Infants of cocaine users are more likely to be preterm and depressed at birth and to have a low birth weight. Cocaine use, through the above-noted effects, increases the need for prenatal care while simultaneously decreasing the likelihood that it will be obtained. (AM J OBSTET GYNECOL 1991;164:625-30.)

Key words: Cocaine, prenatal care, birth weight, prematurity

The use of cocaine has increased markedly among young adults over the past 10 years.[1] This increase has been most notable in inner-city communities, where it has also been frequently reported among pregnant women.[2] The adverse effects of perinatal cocaine use have been widely described and include increases in low birth weight and prematurity rates and smaller head circumferences among exposed neonates.[3-6]

Most reports on cocaine use in pregnancy either have limited their study populations to women attending drug treatment centers or have relied on voluntary participation by study subjects.[3,6] The latter approach may be subject to ascertainment bias, which makes it difficult to assess the actual extent of drug use in a community. In addition, this approach may mask important social consequences of drug use, since unregistered patients would be excluded from analyses.

In an attempt to accurately define the scope of the problem of prenatal cocaine use in an inner-city community, to develop a profile of the pregnant cocaine user, and to study the consequences of recent drug use on perinatal outcome, the following study was undertaken.

From the Departments of Obstetrics and Gynecology,[a] Preventive Medicine,[b] Pathology,[c] and Pediatrics[d] at The State University of New York Health Science Center.

Material and methods

Thirteen hundred thirty-one women who were delivered of an infant at a municipal hospital in New York City between Oct. 18, 1988, and March 1, 1989, were eligible for entry into this study. Entry criteria were admission and/or delivery on a shift staffed

by study personnel. Specimens obtained for routine urinalysis from these parturient women were saved and given code numbers. All samples were collected within 24 hours of admission to the labor and delivery unit. They were then refrigerated and were transported within 48 hours to the institution's toxicology laboratory. Twenty patients who were delivered of their infants on these shifts were not included because they could not void while study personnel were available to collect urine.

Information that is routinely collected from parturients was recorded on data sheets, which were given the same code numbers as those of the respective urine specimens. No patient identifiers remained on data sheets, and drug screening results were never linked to patient names.

Data collected included demographic information (ethnic background, socioeconomic status, etc.); history of drug use (cocaine, marijuana, heroin, alcohol, tobacco); and pregnancy outcome measures (birth weight, gestational age as determined by last menstrual period and ultrasonogram when available, Apgar scores, mode of delivery, abruptio placentae, meconium, fetal distress).

Patients who were discharged before the research staff were able to collect the study data (for example, those who gave birth before staff off days) were not included in data analyses ($n = 200$), which left the 1111 evaluable patients that constituted the study population.

During several shifts per week, study pediatricians assessed all newborns. Pediatric assessment included head circumference, length, and gestational age based on physical examination. Data on these children were given a code number that was matched to the data for respective mothers. Pediatricians' assessments were available on 846 of the study patients. As per routine hospital protocol, urine specimens were collected for toxicologic testing on infants whom the pediatricians suspected had been exposed to a drug of abuse in utero, on either clinical or historical grounds. Two hundred twenty-seven infants, whose mothers' urine specimens had been tested, were tested for drug exposure (unpublished data). The results of these findings are the subject of a separate report. In summary, demographic and obstetric data and information on drug use were available on 1111 patients. Matched pediatric assessments were available on 846 newborns. Since gestational age based on obstetric history in a population with large numbers of unregistered patients might be somewhat unreliable, analysis with the use of gestational age was restricted to the subset from whom gestational age based on pediatric assessment was available ($n = 846$).

Laboratory techniques

Toxicology. Urine screening for illicit drugs was performed with a homogeneous enzyme-multiplied immunoassay technique (Syva Emit d.a.u., Syva Co., Palo Alto) for cannabinoid, cocaine, and opiate assays. Testing was done on a model 705 analyzer (Hitachi Co.) at room temperature (20° to 25° C). This technique has been described elsewhere[7-14]; details are available on request.

All Emit-positive test specimens were retested for confirmation by gas chromatography–mass spectroscopy. Urine samples from mothers were regularly tested the day of accession. Late specimens were refrigerated overnight and were tested the next morning. Positive specimens were stored frozen at −20° C.

Statistical methods. The study design was cross-sectional and focused on the association between the prevalence of cocaine use and various outcome measures. Continuous outcome data such as birth weight or gestational age were analyzed by multiple regression models. Multiple logistic regression models were used when outcome variables were dichotomized, for example, with an Apgar score <7. Multivariate linear models were constructed to examine the impact of cocaine on several outcomes simultaneously. In these models statistical significance was assessed by Wilk's lambda statistic. Canonical correlations were estimated to measure the strength of these associations. Contingency tables were analyzed by Fisher's test, and permutation distribution of the test statistic was used to obtain the exact probability for a table of any size on the basis of an algorithm in StatXact (Cytel, Cambridge, Mass.).

Results

The prevalence of parturients with cocaine metabolites in the urine was 11.5% (128 of 1111). Metabolites of marijuana, methadone, and other opiates were found in 1.2%, 0.3%, and 1.1% of all patients, respectively. The presence of metabolites of methadone and other opiates was detected in a similar percentage of cocaine users and nonusers. Marijuana metabolites were found more frequently in urine samples that contained cocaine metabolites (0.92% vs 3.1%; $p = 0.053$), although this trend did not reach statistical significance. Cocaine users admitted to cigarette smoking during pregnancy significantly more frequently than did nonusers (73% vs 14.3%; $p < 0.001$).

The age distribution of cocaine users was not significantly different from that of nonusers; both groups were clustered in the 21 to 30 age group (Table I). However, the ethnic distribution of the two groups was markedly different. Sixty-six percent of cocaine users were American-born blacks and 14% were from the Caribbean. Only 28% of cocaine nonusers were American-born blacks ($p < 0.001$). The mean parity of cocaine users was 1.83 (±1.65), as compared with 1.14 (±1.31) among nonusers ($p < 0.0001$).

Fifty-one percent of cocaine users had had no prenatal care, as compared with 8.81% of the nonusers.

An additional 29% of cocaine users had inadequate prenatal care (fewer than four visits to any provider) or undocumented prenatal care, as compared with 12% of nonusers ($p < 0.001$).

Drug history was found to be an unreliable predictor of recent drug use; only 54 of 128 patients (42%) with cocaine metabolites in the urine admitted to recent drug intake, which was defined as use within 1 week of admission to the hospital. Fifty-five percent of the same group acknowledged drug use at some time in the more remote past.

The frequency of low-birth-weight infants (those who weighed <2500 gm at birth) was 40.6% among cocaine users and 12% among nonusers ($p < 0.0001$). The differences in mean birth weight were also significant (2560 ± 778 vs 3151 ± 699 gm; $p < 0.001$). Significant differences were also seen in the incidence of bleeding at the time of admission (4.8% among cocaine users vs 1.5% among nonusers; $p = 0.03$) (Table II). There was a higher percentage of abruptio placentae among cocaine users, but this was not statistically significant (1.59% vs 0.41%; $p = 0.2$).

Significant differences were seen in the frequency of low Apgar score (<7 at 5 minutes; 12.5% among users and 3.2% among nonusers). Table III shows the results of logistic regression analysis for cocaine use and 5-minute Apgar scores <7, adjusting for several potential confounders. Cocaine use was the strongest predictor of a low Apgar score, with exposed infants 2.7 times more likely to receive a low score ($p < 0.01$). This was unchanged even after adjusting for gestational age.

Rates of other complications did not differ significantly between cocaine users and nonusers. These complications included premature rupture of membranes (13.0 vs 7.5; $p = 0.053$), chronic hypertension (3.4 vs 5.7; $p = 0.389$), fetal distress (19.0 vs 13.3; $p = 0.148$), meconium-stained amniotic fluid (26.9 vs 20.2; $p = 0.124$), and cesarean delivery (17.3 vs 16.9; $p = 0.90$) (Table II).

Table IV shows the results of the regression analysis for birth weight both with and without gestational age as a covariable. Because gestational age based on obstetric history in this population might be somewhat unreliable, analysis with gestational age was performed for the subset of patients from whom gestational age based on pediatric assessment was available ($n = 639$). Cocaine use was significantly associated with low birth weight (−382 gm) after adjusting for age, parity, alcohol use, cigarette use, hypertension, and prenatal care. As we expected, maternal cigarette smoking, hypertension, and absence of prenatal care each significantly reduced birth weight. After adjustment for gestation, the impact of cocaine was greatly reduced (−77.7 gm), although it was still statistically significant. Cigarette smoking remained a powerful fetal growth retardant (−104.4 gm), even after adjustment for gestational age. Absence of prenatal care did not have a significant impact on birth weight after adjustment was made for gestational age ($p = 0.296$).

Table I. Maternal characteristics of recent cocaine users and nonusers

Maternal characteristic	*Users (%) (n = 128)*	*Nonusers (%) (n = 983)*	*p Value*
Age (yr)	26.7 ± 4.62	25.5 ± 6.17	0.03
Ethnicity (%)			
Black (American)	66.4	28.0	<0.0001
Black (African)	—	2.1	
Black (Caribbean)	10.2	26.8	
Black (unknown)	10.2	7.0

Inadequate care/not documented	19.6	12.3	<0.0001

Gestational age as determined by pediatricians was itself significantly reduced in cocaine users (−0.93 weeks; $p < 0.01$), as were the head circumference (−0.64 cm; $p = 0.04$) and length (−1.23 cm; $p = 0.02$) of the infants of users (Table V). The association between cocaine use and infant head circumference (−0.16; $p = 0.54$) and length (−0.47; $p = 0.24$) was no longer significant after adjustment for gestational age.

When pediatric assessments (head circumference, birth weight, length, and gestation) were examined simultaneously, independent variables that significantly reduced growth included cigarette smoking, (canonical correlation = .0.19; $p = 0.002$), hypertension (canonical correlation = 0.15; $p = 0.03$), and cocaine use (canonical correlation = 0.13; $p = 0.02$). When the trends noted above were adjusted for gestational age, they remained the same, although only cigarette smoking remained a statistically significant growth retardant (canonical correlation = 0.154, $p = 0.001$).

Among patients with cocaine metabolites in the urine, the mean infant birth weight was smaller among those mothers who admitted to drug use (2303 vs 2669 gm; $p = 0.02$). This difference remained significant after adjustment for age and parity. There were no dif-

Comment

We found that 11.5% of parturients in an inner-city hospital had cocaine metabolites in the urine. Furthermore, cocaine appeared to be the most commonly used illicit drug; other illicit substances such as marijuana, methadone, and opiates were found in a much smaller number of patients. We also saw a strong association between recent cocaine use, poor obstetric outcomes, high parity, and failure to utilize prenatal services.

Several investigators have recently focused on the use of cocaine in pregnancy,[5, 6, 15, 16] but few data on the prevalence of cocaine use in an unselected general obstetric population are available.[5, 16] Researchers from Boston City Hospital[5] reported on drug use among a group of urban patients but excluded patients who had not sought prenatal care. In addition, patients in the Boston City Hospital study had the option of not being screened; 8% refused to participate. Another study by Neerhof et al.[6] evaluated patients at the time of delivery but did not cite the percent of unregistered patients included in their cohort; in addition, patients in this study had consented to entry, which introduced the possibility of ascertainment bias. In a nonselected population, we found a higher prevalence of cocaine use (11.5%) than did the investigators mentioned.

Our data on perinatal outcome confirm earlier reports. Previously described effects on birth weight, gestational age, Apgar scores, and intrapartum bleeding were noted. Other authors,[6] for example, have shown an association between cocaine use and preterm delivery, low birth weights,[5, 6] and premature rupture of membranes. We found that cocaine was associated with a 382 gm decrease in birth weight but that cigarette smoking independently reduced birth weight by an additional 125 gm. A major biologic effect of cocaine appeared to be that of shortening gestational age. Cigarette smoking exerted a negative effect on birth weight in all gestational ages.

Potentially, one of the most harmful effects of cocaine use, in addition to its biologic consequences, is its social consequences. Eighty percent of recent cocaine users in our study had had either no prenatal care or inadequate prenatal care. MacGregor et al.[17] tested the hypothesis that among cocaine-using women who were delivered of infants at their institution, those who had received comprehensive prenatal care had better perinatal outcomes than did those who had received little or no prenatal care.

Our study design also allowed us to evaluate unregistered patients. They were found to be at significantly higher risk for illicit drug use than were registered patients. Indeed, lack of care was a useful marker for cocaine use, in that 43% of patients with no prenatal care had cocaine metabolites in the urine. Patient history was, in fact, no more reliable than unregistered

status in predicting toxicology results. Only 41% of patients with cocaine metabolites in the urine acknowledged cocaine use within 1 week of delivery. Those who did acknowledge use, however, may represent a group of particular risk, since they were delivered of smaller infants than were cocaine users who did not acknowledge use.

We have also found a significantly higher parity among cocaine users, which is consistent with reports of Neerhof et al.[6] This finding may be related to the fact that in poor communities women addicted to cocaine (particularly "crack") are reported to barter sex for drugs,[18] which could result in unwanted pregnancy. Increased parity among drug users has potentially devastating social consequences. Children born to parents whose addiction leaves them incapable of caring for them have already overloaded the foster care system in New York City; the census of these children increased from 16,000 in 1984 to 24,000 in 1989. These figures do include an additional 10,000 children who were being cared for by relatives other than their parents.[19]

Urine toxicology (as opposed to history), which was used to determine a patient's drug use status, subjects the study to misclassification bias. Individuals who used cocaine during pregnancy but not recently enough to be detected at the time of delivery would be classified as nonusers. Only studies that evaluated the regular urine tests of patients throughout pregnancy could avoid this bias. Cross-sectional studies at term, however, have the advantage of including unregistered patients and hence provide a description of outcomes in a subpopulation that is at particular risk. In any case the misclassification described would bias the study toward the null hypothesis and would suggest even stronger associations than those noted here.

In summary, cocaine use among parturients in the

inner-city community studied has reached epidemic proportions. Previously reported effects on low birth weight, prematurity rates, and low Apgar scores have been confirmed in this report. In addition, we found a striking association between cocaine use and failure to utilize prenatal services. This finding, along with the increased parity of women using cocaine in pregnancy, portends an increasing burden for social service institutions in urban settings. It is clear that programs designed to detect and treat pregnant cocaine users will have to use innovative means of outreach before the consequences of prenatal addiction can be addressed in any effective manner.

The value of squamous cell carcinoma antigen in patients with locally advanced cervical cancer undergoing neoadjuvant chemotherapy

Giovanni Scambia, MD, Pierluigi Benedetti Panici, MD, Gabriela Baiocchi, MD, Mariangela Amoroso, MD, Elvira Foti, MD, Stefano Greggi, MD, and Salvatore Mancuso, MD

Rome, Italy

Serum levels of squamous cell carcinoma antigen were measured in 688 samples from 119 patients with cervical cancer. Ninety-seven patients had primary tumors and 22 had recurrent disease. Serum samples were obtained before each cycle of chemotherapy, before surgery, at least 4 weeks after surgery, and at 2- to 3-month intervals during follow-up from 78 of the patients with locally advanced cervical cancer who were receiving neoadjuvant chemotherapy. Squamous cell carcinoma antigen serum levels were elevated (>2.5 ng/ml) in 71% of the patients with primary tumors and in 77% of the patients with recurrent carcinomas. The percentage of positivity increased significantly with stage ($p = 0.03$) and was higher in squamous cell tumors than in adenocarcinomas ($p < 0.001$). Pretreatment squamous cell carcinoma antigen levels were not predictive of neoadjuvant chemotherapy response; however, the serial measurement during chemotherapy showed a good correlation with clinical response. In the patients who had surgery, squamous cell carcinoma antigen positivity did not correlate to pathologic findings (lymph node status, cervical and parametrial infiltration). Disease-free survival was significantly longer in patients with squamous cell carcinoma antigen pretreatment values that were lower than 5 ng/ml, compared with patients with marker higher than 5 ng/ml ($p < 0.01$). Abnormal squamous cell carcinoma antigen serum levels preceded the clinical detection of recurrence in eight of 11 patients with a median lead time of 5 months. (Am J Obstet Gynecol 1991;164:631-6.)

Key words: Squamous cell carcinoma antigen, cervical cancer, tumor markers, gynecologic malignancies

The management of patients with cervical cancer is hindered by limitations in clinical staging, assessment of response to therapy, and early detection of tumor recurrence. The identification of sensitive tumor markers may overcome these difficulties by permitting a more timely alternative or additional therapy.

Squamous cell carcinoma antigen, a subfraction of the TA-4 antigen, appears to be the most promising of the tumor markers that have been proposed for cervical cancer.[1-9] Although squamous cell carcinoma antigen is not useful for the early diagnosis of cervical cancer,[7-9] recent data demonstrate that in patients with invasive disease, this antigen could be employed in monitoring the response to therapy[6-9] as well as in detecting recurrences.[5, 9] However, until now, only few data are available on the serial measurements of the antigen over long periods of time in a large population of patients. In particular, only a few anecdotal cases have been reported concerning squamous cell carcinoma antigen evaluations during chemotherapy.[6-8] Moreover, in spite of a previous paper by Kato et al.,[10] which suggests that TA-4 might have a prognostic significance in cervical cancer, no other studies have addressed this point. Therefore the exact role of squamous cell carcinoma antigen in the proper management of patients with cervical cancer is still to be assessed.

We report here the experience of the Department of Gynecology of the Catholic University in the measurement of squamous cell carcinoma antigen in patients with invasive cervical cancer. Our study focuses on a large group of patients with locally advanced disease who had neoadjuvant chemotherapy followed by radical surgery[11, 12] and in whom squamous cell carcinoma antigen serum levels were serially measured for a period of 5 to 48 months. The data were analyzed to highlight the following points: (1) to determine whether squamous cell carcinoma antigen is an indicator of chemosensitivity and whether serial measurements of the antigen are a useful tool in monitoring the response to chemotherapy; (2) to ascertain whether

pretreatment squamous cell carcinoma antigen levels have a prognostic significance; (3) to clarify the role of the antigen in the detection of recurrent disease.

Patients and methods

Our study included 688 serum samples from 119 patients (median age, 51 years; range, 31 to 74 years) with invasive cervical cancer, who were admitted to our Department from December 1987 to November 1989. Twelve patients had stage I disease, 43 had stage II, 35 had stage III, and 7 had stage IV, according to the International Federation of Gynecology and Obstetrics classification. Twenty-two had a recurrent disease. Diagnosis was always confirmed by histologic examination. Histologically, these tumors were classified as squamous in 79 patients and as adenocarcinomas in 18 patients. According to the degree of histologic differentiation tumors were found to be well, moderately, and poorly differentiated in 13, 46, and 38 patients, respectively. Seventy-eight patients with locally advanced cervical carcinoma (stage IB or IIA, tumor volume >4 cm, IIB, and III) received neoadjuvant chemotherapy according to two different schedules. The first schedule (64 patients) consisted of three cycles of cisplatin (100 mg/m^2), bleomycin (15 mg), and methotrexate (300 mg/m^2).[11, 12] Fourteen patients took part in a subsequent pilot study and received a single cycle of cisplatin (200 mg/m^2)[13] and bleomycin (30 mg). Cervical tumor size was measured by the combination of gynecologic examination, colposcopy, and pelvic ultrasonography. Stability, progression, and regression of disease were defined according to World Health Organization criteria.[14] Both protocols of neoadjuvant chemotherapy and radical surgery were approved by the Investigational Review Board, and patients gave their informed consent.

Serum samples were obtained before each cycle of chemotherapy, before surgery, at least 4 weeks after surgery, and at 2-month intervals during follow-up. Venous blood samples for marker determination were separated by centrifugation and aliquots were stored at −20° C until assayed. Squamous cell carcinoma antigen assay was performed with a commercially available kit (SCC RIA kit, Abbott Laboratories Diagnostic Div., Abbott Park, Ill.). Intraassay and interassay variations were 6.2% and 8.5%, respectively. The upper normal level was taken as 2.5 ng/ml. With this cutoff value, 62 of 66 healthy female subjects had normal marker values.

Marker titers were defined as increasing or decreasing when changes were greater than 50% of the previous value. χ^2 Test and Fisher's exact test were used to evaluate the distribution of marker values according to different variables. Life-table analysis was performed with the Kaplan and Meyer method,[15] and curves were examined by means of the z test.[16]

Results

Pretreatment evaluation. Table I shows the distribution of pretreatment squamous cell carcinoma antigen levels in relation to stage, histotype, and grade of tumor differentiation. Among patients with primary tumors, squamous cell carcinoma antigen values were found to be above 2.5 or 5 ng/ml in 71% and 45% of the cases, respectively. In these patients the percentage of positivity increased significantly with stage (p =

0.03). Abnormal squamous cell carcinoma antigen serum values were found in 77% of patients with recurrent disease. As previously reported,[7-9] squamous cell carcinoma antigen was more frequently expressed in squamous cell tumors than in adenocarcinomas ($p < 0.001$). Squamous cell carcinoma antigen positivity was not significantly related to histologic grading.

Squamous cell carcinoma antigen during neoadjuvant chemotherapy. Among our study population, 78 patients with locally advanced inoperable cervical cancer had squamous cell carcinoma antigen levels measured before and during neoadjuvant chemotherapy. Sixty-five of these patients achieved a clinical response (10 complete and 55 partial), whereas the remaining 13 had no change or progression of disease.

As shown in Table II pretreatment squamous cell carcinoma antigen levels were not predictive of chemotherapy response. However, in the 49 patients with positive pretreatment squamous cell carcinoma antigen levels the changes of marker values that were measured 2 weeks after the end of chemotherapy with respect to pretreatment values were closely related to the clinical course of the disease (Table III). The overall correlation between the clinical course of the disease and the variation of squamous cell carcinoma antigen levels was 84% (41 of 49). Interestingly, the changes of squamous cell carcinoma antigen levels after two cycles of chemotherapy predicted the clinical outcome in 86% of cases. On the other hand, after one cycle of chemotherapy, the predictive value of the squamous cell carcinoma antigen assay was only 57% (data not shown). This low figure is due to the fact that in eight patients who achieved partial response at the end of the three cycles of treatment squamous cell carcinoma antigen levels remained stable after the first cycle, whereas in seven patients squamous cell carcinoma antigen levels initially decreased even though the final clinical evaluation showed no change of disease.

Squamous cell carcinoma antigen levels and pathologic findings at surgery. In sixty-five patients surgery was possible after neoadjuvant chemotherapy and underwent surgery that consisted of type III-IV radical hysterectomy with systematic paraaortic and pelvic lymphadenectomy. Table IV shows the distribution of squamous cell carcinoma antigen values according to some of the most important pathologic findings. It appears that squamous cell carcinoma antigen positivity measured both before and after neoadjuvant chemotherapy did not correlate with lymph node status, depth of tumor penetration, or parametrial involvement.

Squamous cell carcinoma antigen levels and prognosis of cervical cancer. Fig. 1 shows that among patients who received neoadjuvant chemotherapy the disease-free interval curve significantly differed ($p < 0.01$) according to squamous cell carcinoma antigen pretreatment values. Moreover, when pretreatment squamous cell carcinoma antigen values were analyzed in relation to recurrence of disease, it appeared that

higher antigen levels were present in patients who had recurrences than in those who did not. With a cutoff value of 5 ng/ml (Table V) recurrence rate was 73% in patients with positive squamous cell carcinoma antigen levels compared with 41% in those with negative values ($p = 0.05$). Even though the number of patients is still too small to allow final conclusions, the difference between patients with positive squamous cell carcinoma antigen and those with negative levels persisted even when patients were subdivided by stage, although it reached a statistical significance only for patients who had stage III carcinoma ($p = 0.03$).

Squamous cell carcinoma antigen and detection of recurrences. Over the median follow-up period of 25 months (range, 5 to 48 months) after surgery, 11 patients had recurrent disease. As shown in Fig. 2, elevated serum values of squamous cell carcinoma antigen preceded the clinical detection of recurrences in eight cases with a median lead time of 5 months. In two of three patients with negative pretreatment squamous cell carcinoma antigen levels, an abnormal value was detected at the time of the clinical diagnosis. In the last patient the squamous cell carcinoma antigen level never rose.

Comment

Our study demonstrates that squamous cell carcinoma antigen represents a useful biochemical diagnostic tool for the proper management of patients with invasive cervical cancer.

Pretreatment squamous cell carcinoma antigen levels did not differ among patients who responded and those who did not respond to neoadjuvant chemotherapy, which suggests that squamous cell carcinoma antigen expression is not an indicator of chemosensitivity. However, in the large series of patients with locally advanced tumors who were examined in this study, squamous cell carcinoma antigen proved to be very well correlated with the clinical response to neoadjuvant chemotherapy. Interestingly, the changes of squamous cell carcinoma antigen levels after two of the three planned cycles of chemotherapy were good predictors of the final clinical outcome. This suggests that the serial assessment of squamous cell carcinoma antigen concen-

trations during neoadjuvant chemotherapy may add important clinical information that would lead to timely use of alternative or additional therapies.

It is worth mentioning, however, that during the early phases of chemotherapy, misleading results can be found. The initial fall of squamous cell carcinoma antigen levels in patients who are not responding to neoadjuvant chemotherapy suggests that in some cases a tumor component may initially respond to therapy.

Squamous cell carcinoma antigen might have a prognostic role in cervical cancer. Patients with positive squamous cell carcinoma antigen serum titers have a higher recurrence rate and a reduced disease-free interval compared with patients with negative squamous cell carcinoma antigen titers. This is consistent with observations made by Kato et al.[10] and more recently by Maiman et al.[9] It remains to be demonstrated whether squamous cell carcinoma antigen measurement may represent a prognostic factor that is independent from other variables. To obtain this confirmation, work is in progress on a large patient population. However, the finding that the difference in the recurrence rate be-

tween patients with positive SCC and those with negative SCC stage III is still statistically significant seems to be encouraging. Moreover, the lack of correlation between squamous cell carcinoma antigen levels and some important pathologic prognostic factors, such as parametrial involvement, lymph node status, and depth of tumor penetration,[17] further supports this hypothesis.

Squamous cell carcinoma antigen measurement proved to be very useful in the detection of recurrent disease after surgery. In patients with high pretreatment squamous cell carcinoma antigen levels, the elevation of the antigen preceded the clinical detection of disease with a median lead time of 5 months. This confirms previous observations made by Maiman et al.[9] who reported that squamous cell carcinoma antigen preceded recurrence by an average of 5 months. Previously, Kato et al.[5] reported that elevated TA-4 levels preceded the clinical detection of disease recurrence in 11 of 17 patients.

Our study clearly shows that, at least in patients with locally advanced cervical cancer, the serial measurement of squamous cell carcinoma antigen is particularly useful in those patients with high pretreatment values. In fact, among patients with negative squamous cell carcinoma antigen values, elevation of squamous cell carcinoma antigen was detected in two cases only when disease recurred after surgery. This conclusion cannot be applied to patients with early cervical lesions. In such cases, even though tumor cells can express squamous cell carcinoma antigen, the serum antigen titers could be within the normal range because of the low tumor burden. Therefore in these cases an immunohistochemical evaluation of squamous cell carcinoma antigen expression on the tumor specimens could be more useful to select candidate patients for squamous cell carcinoma antigen monitoring during therapy and follow-up.

In conclusion, our study provides evidence that the squamous cell carcinoma antigen serum assay should be routinely assessed in patients with invasive cervical cancer. Serial measurements of the antigen seem to be useful to monitor response to therapy and might also influence clinical decisions concerning the discontinuation and change of therapy as well as the early use of second-line therapies. Further clinical trials should now verify the role of squamous cell carcinoma antigen levels as a prognostic factor of cervical cancer.

Neonatal complications at term as related to the degree of umbilical artery acidemia

Carey L. Winkler, MD, John C. Hauth, MD, J. Martin Tucker, MD, John Owen, MD, and Cynthia G. Brumfield, MD

Birmingham, Alabama

The degree of umbilical arterial acidemia associated with immediate newborn morbidity has not been determined. Therefore we compared 358 term infants with umbilical artery acidemia (pH < 7.20) with 358 term, nonacidotic matched control infants, to evaluate immediate neonatal complications in both groups. Nonacidotic was defined as an umbilical artery pH ≥7.20. Complications included seizures, persistent hypotonia, and/or signs of end-organ damage such as renal or cardiac dysfunction. None of the 693 newborns with an umbilical artery pH ≥7.00 had such complications. Two of 23 infants with an umbilical artery pH <7.00 had sequelae related to intrapartum asphyxia. In these two infants the umbilical artery pH was <7.00, the 1-minute and 5-minute Apgar scores were ≤3 and the acidemia was metabolic in nature. (Am J Obstet Gynecol 1991;164:637-41.)

Key words: Acidemia, complications, neonatal, term

Until recently, peripartum asphyxia was commonly believed to be the primary cause of cerebral palsy, mental retardation, and other forms of neurological dysfunction. More recent studies now suggest that the causes of cerebral palsy are unknown and that intrapartum events may account for only a small fraction of such cases.[1-5] In spite of the use of continuous electronic fetal heart rate monitoring systems and an ever-increasing cesarean section rate, the incidence of cerebral palsy has remained essentially unchanged for the last two decades.[6]

Asphyxia is defined as cessation of gas exchange, with subsequent hypoxia and hypercarbia. In utero, total cessation of gas exchange is rare, but varying degrees of hypoxia and transient interference with maternal-fetal respiratory exchange are common in all labors. If significant hypoxemia occurs, the fetus will utilize anaerobic glycolysis to meet its energy needs. The subsequent formation of nonvolatile acids such as lactic acid will result in a decrease in the blood pH of the fetus. Various investigators have established normal ranges for umbilical artery pH and blood gas values.[7-12] Most have found that the mean umbilical artery pH ranges from 7.25 to 7.30, with 2 SD below the mean ranging from 7.15 to 7.20. Thorp et al.[7] have reported a large series in which normal ranges for umbilical cord blood gas levels at term were established. They determined the mean umbilical artery pH to be 7.24, with SD of 0.07 pH units. Thus in their series a pH of 7.10 was a statistically low pH, i.e., <2 SD below the mean umbilical artery pH. Ruth and Raivio[8] selected an umbilical artery pH of <7.16 as <2 SD below the mean. We have previously reported that 2 SD below the mean umbilical artery pH is 7.18.[9] However, the population from which this figure was derived was selected to have been at term gestation, to have had a spontaneous vaginal delivery, and to have had a normal fetal heart rate baseline and variability in the second stage of labor. Wible et al.[10] defined a low umbilical artery pH as <7.20. Thus, despite the traditional definition of umbilical artery acidemia as a pH <7.20,[13] most recognize that this level is arbitrarily high and may range as low as the 7.10 suggested by Thorp et al.[7] No one has demonstrated any significant biologic correlation between these statistical definitions and the subsequent immediate neonatal performance. We have surmised, as did Gilstrap et al.,[14] that at least one partial explanation for the apparent lack of correlation of umbilical artery cord gas parameters and immediate neonatal asphyctic sequelae is the utilization of the arbitrarily high values of normal and standard deviation for the umbilical artery pH. Thus the denominator has been diluted with the normal values of normal newborns. The inclusion of newborns who have a statistically significant low pH value (with the use of cutoff values as low as 7.10, 7.15, 7.18, or 7.20) has had little correlation to fetal biologic damage at term gestation, as reflected by a newborn course compatible with intrapartum asphyxia. We have hypothesized that the effect of an intrapartum period of hypoxia or asphyxia that is sufficient to cause pro-

tracted fetal and neonatal damage is not a linear function. Rather we have observed that only below a certain umbilical artery pH, with a metabolic component to the acidemia and with a low 5-minute Apgar score, will the incidence of newborn asphycitic complications increase.

We sought to determine the correlation between the degree of umbilical artery acidemia, type of acidemia, and Apgar scores and the immediate neonatal complications that have commonly been correlated with adverse neurologic outcomes.[15, 16]

Material and methods

This study is based on 2764 term deliveries that occurred from October 1987 to April 1989. In all of these deliveries, paried umbilical artery and vein blood gas determinations were made. A group of fetuses was selected whose gestational age was ≥37 weeks, who had paired umbilical artery and vein cord gas samples, and whose umbilical artery pH was <7.20. During this time period, 358 mother-infant pairs met these criteria, and their charts were retrospectively reviewed. The control group consisted of 358 mother-infant pairs with delivery occurring during the same time period with similar inclusion criteria, except that the umbilical artery pH was ≥7.20. Each acidotic fetus was matched with a control by obtaining the next subsequent fetus matched for mode of delivery and indication for operative delivery.

Blood samples were drawn from a doubly clamped segment of umbilical cord into a 1 ml syringe flushed with 1/1000 heparin solution and placed on ice. Blood gas determinations were performed with an ABL 330 blood gas analyzer (Radiometer, Copenhagen). Umbilical artery acidemia was classified as follows[17]: metabolic—umbilical artery pH <7.20, P_{CO_2} < 65 mm Hg, and bicarbonate ≤17 mEq/L; respiratory—umbilical artery pH <7.20, P_{CO_2} ≥65 mm Hg, and bicarbonate >17 mEq/L; mixed—umbilical artery pH <7.20, with P_{CO_2} ≥65 mm Hg and bicarbonate ≤17 mEq/L or with P_{CO_2} <65 mm Hg and bicarbonate >17 mEq/L.

Maternal records were reviewed for antenatal complications, mode of delivery, use of oxytocin, and type of anesthesia. Neonatal charts were reviewed for Apgar score, birth weight, and immediate neonatal complications known to be associated with intrapartum asphyxia. These complications included neonatal seizures, persistent hypotonia, and evidence of end-organ dysfunction such as acute cardiac or renal failure.

The data were analyzed using the SAS statistical software package (Statistical Analysis Systems, Cary, N.C.). The Student t test, χ^2, and analysis of variance were used where appropriate. Statistical significance was defined as a p value ≤0.05.

Results

There was no significant difference between the two groups as to parity, race, use of oxytocin, gestational age at delivery, birth weight, sex, operative delivery, indication for operative delivery, diagnosis of fetal distress, or neonatal complications (Table I). There were two neonatal deaths in the control group, one from lethal anomalies, and the other from group B streptococcus sepsis. One infant, a thanatophoric dwarf with secondary respiratory insufficiency, died among the group with acidosis.

Three hundred fifty-eight of 2764 term newborns had an umbilical artery pH of <7.20. The mean umbilical artery pH of the study population was 7.13 (range 6.65 to 7.19), and that of the control population was 7.26 ($p < 0.001$). Sixty-eight newborns (19.0%) had an umbilical artery pH <7.10, with 23 (6.4%) of these pH values <7.00. The average 1-minute and 5-minute Apgar scores were significantly lower in the 23 newborns with an umbilical artery pH <7.00 (Fig. 1) when compared with those 693 whose pH exceeded 7.00. The number of Apgar scores ≤3 at 1 minute was significantly greater in the acidemia group than in the control group (18 vs 7, respectively, $p = 0.025$). This difference in the 1-minute Apgar score mostly occurred as the result of including those newborns with an umbilical artery pH <7.00. At 1 minute, 7 of 23 newborns (30.4%) with an umbilical artery pH <7.00 had an Apgar score ≤3, as compared with 11 of 335 newborns (3.1%) with a pH of 7.00 to 7.19 and 7 of 358 newborns (2.0%) with a pH ≥7.20. At 5 minutes the Apgar scores for all pH groups were not significantly different.

Fifty-five (15.4%) of the study population had a metabolic acidemia, 156 (43.6%) a respiratory acidemia, and 147 (41.1%) a mixed pattern. The type of acidemia was not associated with any significant difference in the incidence of low Apgar scores at 1 or 5 minutes as compared among the group with acidemia or with the control population. Asphyctic newborn complications occurred only in the mixed group (Table II).

For the acidemia group, the distribution of the different types of acidemia (metabolic, respiratory, or mixed) were equal throughout the pH ranges. Only two infants in the acidemia group had asphyctic complications. A description of each of these cases follows.

Case reports

Case 1. After an uncomplicated prenatal course the patient presented to the antepartum clinic with severe hypertension, proteinuria, and headache. On admission to the hospital, after a 4 gm intravenous bolus of magnesium sulfate, the patient had a tonic-clonic seizure that continued in spite of further magnesium and valium therapy. Fetal bradycardia then occurred. General anesthesia was induced to control the convulsions and to permit an emergent cesarean delivery. The 3620

gm female infant was born at term. Apgar scores were 2 at 1 minute and 4 at 5 minutes. The umbilical cord gases showed a pH of 6.65, P_{O_2} of 2 mm Hg, P_{CO_2} of 169 mm Hg, and bicarbonate of 15 mEq/L. The infant needed oxygen for 2 days but subsequently died after heart failure from severe tricuspid valve regurgitation caused by ischemic necrosis of the papillary muscle after the neonatal period. Review by our neonatal faculty concluded that intrapartum hypoxia and asphyxia resulted in irreversible fetal cardiac damage.

Case 2. The patient was admitted at term for induction of labor because of severe oligohydramnios. During labor, mild to moderate variable fetal heart rate decelerations occurred, followed by persistent severe bradycardia. An emergency cesarean section was performed. The infant weighed 3620 gm and had an Apgar score of 1 at 1 minute and at 5 minutes. The umbilical artery cord blood showed a pH of 6.96, P_{CO_2} of 89 mm HG, P_{O_2} 8 of mm Hg, and bicarbonate of 16 mEq/L. The neonatal course was complicated by acute renal failure, major motor seizures, and a requirement for supplemental oxygen for 2 days.

Comment

The causes of cerebral palsy and other neurologic disorders remain unknown. Previously, many infants with these dysfunctions were thought to have had intrapartum asphyxia. However, it has become apparent that at most, only 10% of the incidence of cerebral palsy results from intrapartum asphyxia.[1, 2, 4, 5] In spite of numerous advances in the evaluation of the neonate in the immediate newborn period, we are still unable to predict adverse neurologic sequelae. Moreover, the degree of severity of intrapartum asphyxia-acidemia that is required to cause neurologic damage to the fetus is still unknown.

The presence of neonatal hypoxic encephalopathy (major motor seizures, persistent hypotonia) identifies those infants most likely to have long-term neurologic disorders.[16, 18] The presence of hypoxic encephalopathy, however, identifies only those with the most severe asphyxia. A marker of more subtle changes is desirable. Many authors have shown that the 1-minute and 5-minute Apgar scores are not useful as markers for as-

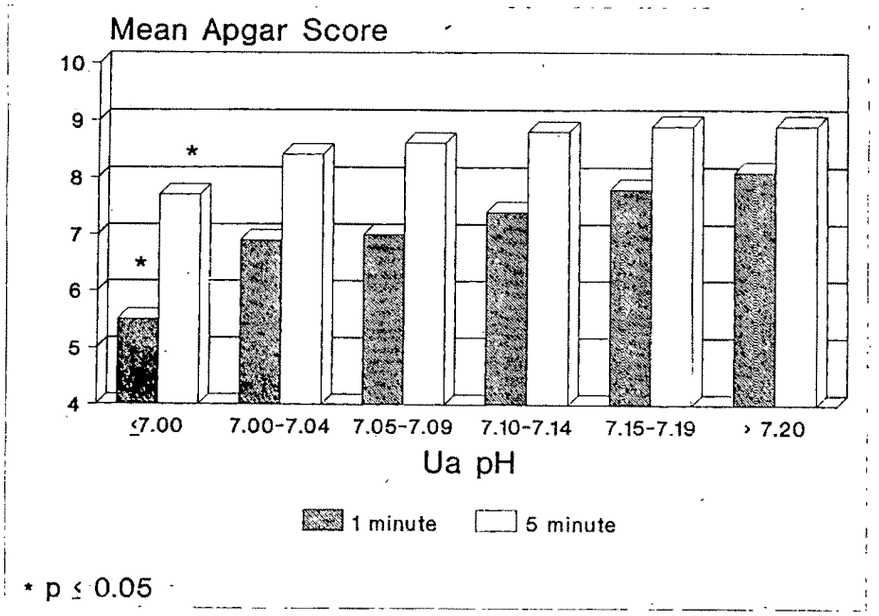

Fig. 1. Low Apgar scores as related to level of umbilical artery pH.

phyxia, since they cannot be used to accurately predict neurologic problems during infancy.[1-4, 18] Since sustained fetal hypoxia results in acidemia, many researchers have advocated using the level of umbilical artery acidemia as a measure of the severity of the intrapartum hypoxia. Neonatal acidemia is defined as an umbilical artery pH <7.15 or <7.20, because these values are 2 SD below the mean umbilical artery pH of normal infants.[13] However, few reports have correlated either the type or the degree of umbilical artery acidemia with neonatal complications. Gilstrap et al.[14] suggested that newborns are only at risk for immediate complications that result from intrapartum asphyxia when the umbilical artery pH is <7.00 and Apgar scores are ≤3 at both 1 minute and 5 minutes. However, their series evaluated only one umbilical sample. Moreover, in spite of the presence of nonacidotic neonates in the study population, neonates with acidemia were not matched to nonacidemic controls.

The purpose of our review was to ascertain which type and degree of acidemia, if any, places newborns at increased risk for immediate newborn complications. Our review was, by intention, limited to term infants, to eliminate the many confounding variables unique to preterm infants.[8, 19] Our study group was matched with nonacidotic controls to assess the background incidence of complications.

Mean 1-minute and 5-minute Apgar scores were lower when the umbilical artery pH was <7.00. However, if the pH was >7.00, there were no significant differences in Apgar scores when the study population and the control population were compared. The type of umbilical artery acidemia did not predict low Apgar scores, either at 1 minute or at 5 minutes. Asphyctic complications (persistent hypotonia, neonatal seizures, evidence of end-organ damage, or persistently low Apgar scores) occurred in only 2 of the 358 acidotic newborns and were not seen in any members of the control group. Each of the two infants who died had both a severe mixed acidemia and low Apgar scores at 1 minue and at 5 minutes. In spite of the presence of severe acidemia (pH ≤7.00), only 2 of 23 infants (9%) had significant complications. None of the remaining 66 infants with an umbilical artery pH <7.10 manifested ominous signs or symptoms in the neonatal period.

In our series we were unable to demonstrate a statistically significant difference in the incidence of short-term neonatal complications that were attributable to acidosis (2/358 vs 0/358, $p = 0.25$, Fisher's exact test). Therefore we performed a power analysis to determine the difference in acidemic complications that could have been detected in our study population. With an α level of 0.05, this study has an 80% chance of detecting a difference in morbidity of 0.36%, if such a difference actually exists.

Thus we could not confirm that infants born with an umbilical artery pH <7.20 are at greater risk for short-term neonatal complications attributable to intrapartum asphyxia than are those infants with a pH ≥7.20. However, when newborns have a severe acidemia (umbilical artery pH <7.00), especially with a metabolic component, as well as low 1-minute and 5-minute Apgar scores, they may be at increased risk for neonatal complications of the types commonly associated with

neurologic sequelae. Nevertheless the absolute risk is undetermined, since in our series of 358 term acidotic deliveries only 2 of 23 (9%) infants with severe acidemia had newborn complications indicative of intrapartum asphyxia. A larger study of severely acidotic infants would be required to define this risk more precisely.

In summary, the positive predictive value of umbilical cord gas analysis for immediate newborn complications associated with presumed intrapartum hypoxia is poor. However, umbilical artery blood gas analysis is useful in excluding intrapartum asphyxia.

Urinary tract dilatation in pregnancy

Mark A. Brown, MD
Sydney, Australia

Right-sided ureteral and renal pelvis dilatation was observed during routine uterine ultrasonographic examination at 30 weeks' gestation. This continued to progress with the renal pelvis measuring 8.9 cm in diameter at 35 weeks, leading to early delivery. Renal function remained normal and these changes resolved completely after delivery. (Am J Obstet Gynecol 1990;164:641-3.)

Key words: Hydronephrosis, pregnancy, renal pelvis

Dilatation of the ureters and renal pelves are well-recognized accompaniments of normal pregnancy. Numerous studies have sought to determine whether this dilatation is physiologic (a result of ureteral smooth muscle relaxation) or anatomic (a result of compression of the ureter by the fetus, particularly on the right-hand side as it crosses the iliac artery at the pelvic brim) but this issue remains unresolved.[1,2] Surprisingly, in the course of these studies no data were provided to help clinicians recognize what degree of urinary tract dilatation can occur during normal pregnancy and it is therefore difficult to know when such dilatation is evidence of a disease process. We recently managed a case of massive urinary tract dilatation in pregnancy that caused us to deliver the patient early, although the changes resolved completely and spontaneously postpartum.

Case report

A 29-year-old Irish woman attended the antenatal clinic for a routine visit at 30 weeks' gestation in her fourth pregnancy. Her first pregnancy 8 years previously had been complicated by mild pregnancy-induced hypertension and she had since had two normal pregnancies. Ultrasonographic examinations were not performed in any of the previous pregnancies. She had always been in good health and was unaware of any family illnesses. She had not taken any medication throughout this pregnancy, was a nonsmoker, and did not consume alcohol. Routine uterine ultrasonography confirmed her stage of gestation and showed normal fetal anatomy. However, the proximal right ureter was noted to be dilated during this scan and was traced to the renal pelvis. The ureter measured 2 cm in diameter in its proximal portion and the right renal pelvis was 7 cm (Fig. 1). The appearance of the left urinary tract was considered normal. Blood pressure was 120/70 mm Hg, there were no specific urinary tract symptoms, results of urinalysis and urine microscopy were normal, and there was no evidence of urinary tract infection. Serum creatinine level was 0.04 mmol/L and serum electrolyte values were normal.

A repeat scan was made 3 weeks later at which time the renal pelvis had increased to 8.2 cm in diameter (Fig. 1). The patient remained without symptoms and normotensive. Serum creatinine level was 0.06 mmol/L. Two weeks later the right renal pelvis measured 8.9 cm and there was a slight decrease in renal cortical width (Fig. 1). Serum creatinine level was 0.05 mmol/L and blood pressure and urinalysis were normal. Because of the progressive enlargement of the renal pelvis and possible reduction in cortical width, she was admitted to the hospital and labor was induced at 36 weeks' gestation. She was delivered of a male infant who weighed 3175 gm and is well.

Two days postpartum renal ultrasonography showed the right renal pelvis was reduced to 2.6 cm diameter and the ureter in its proximal portion to 1 cm (Fig. 1). An intravenous pyelogram showed enlarged kidneys, 17 cm on the right and 16 cm on the left, with no evidence of urinary tract obstruction or any intrinsic ureteral lesion. Serum creatinine value was 0.05 mmol/L. A further ultrasonogram was obtained 3 months postpartum and showed that kidney size had returned to normal and the renal pelvis and ureter were completely normal.

Comment

This case shows massive dilatation of the right ureter and renal pelvis accompanying normal pregnancy. To our knowledge this degree of urinary tract dilatation has not been reported previously and therefore we considered this to be abnormal for pregnancy and more likely to reflect intrinsic ureteral disease. The fact that these changes resolved so rapidly and completely postpartum prove that they were entirely caused by pregnancy and were not a result of a ureteral lesion. In

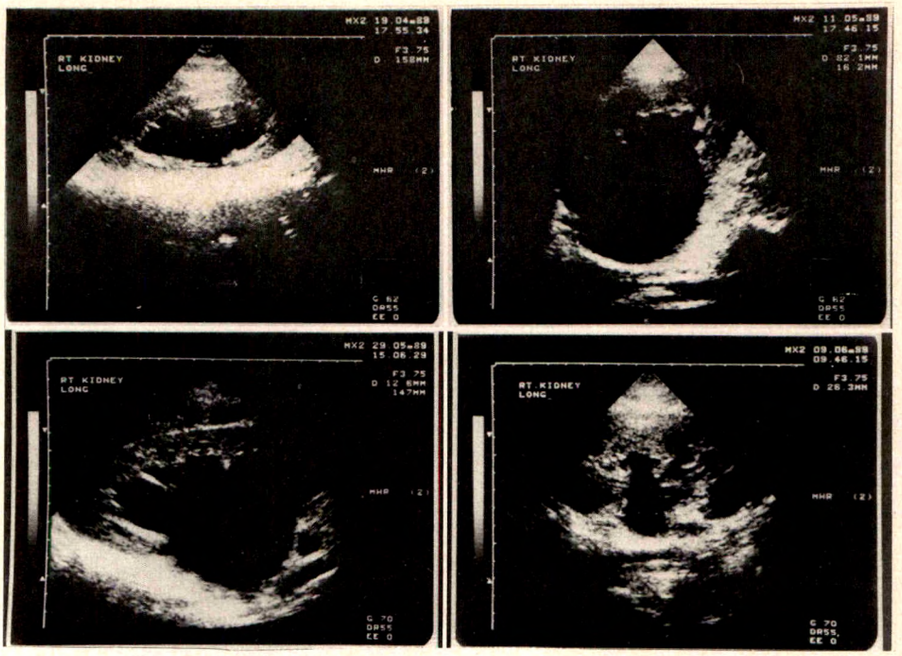

Fig. 1. Renal ultrasonographic recordings at 30 weeks' gestation *(top left)*, 33 weeks *(top right)*, 35 weeks *(bottom left)*, and 2 days postpartum *(bottom right)*. Renal pelvis enlarged from 7 cm at 30 weeks to 8.9 cm at 35 weeks.

retrospect there was no maternal indication for delivery and long-term renal function from the right kidney was unlikely to be jeopardized, so that induction of labor was probably unnecessary.

It is unknown whether such a degree of urinary tract dilatation is common during pregnancy inasmuch as no study has documented the degree of dilatation in a systematic fashion. However, on the basis of this case it seems reasonable to allow pregnancy to progress normally and delivery to occur spontaneously even in the face of such massive ureteral and renal pelvic dilatation in pregnancy, provided that the patient is without symptoms and there is no evidence of impairment of renal function.

Clinical implications of screening for cervical cancer under Medicare

The natural history of cervical cancer in the elderly: What do we know? What do we need to know?

Jeanne Mandelblatt, MD,[a] Clyde Schechter, MD,[b] Marianne Fahs, PhD,[c] and Charlotte Muller, PhD[c]

New York, New York

Despite the recent passage of coverage for Papanicolaou test screening under Medicare, several aspects of the natural history of cervical cancer in the elderly remain uncertain. This article reviews what we know about cervical cancer in elderly women to provide clinicians with the background necessary for assessments of screening recommendations, integration of new data into practice, and development of consensus approaches to screening in the elderly. Two central questions that affect a screening program for the elderly are how long the neoplastic process takes from preinvasive disease to the development of invasive cancer, and how likely is it that a given neoplastic state observed in an elderly woman will, in fact, progress to a more severe state. The ultimate success of the new Medicare benefit will also be affected by the use of Papanicolaou testing, the technique of obtaining the smear, and the adequacy of reporting and follow-up. The expansion of Medicare benefits to include early cervical cancer detection has the potential to improve the quality and the duration of older women's lives. (Am J Obstet Gynecol 1991;164:644-51.)

Key words: Cervical cancer, elderly, Medicare, Papanicolaou smears

Contrary to popular belief, cervical cancer remains an important health problem into old age and most groups now conclude that screening needs to reach older women to be maximally effective in decreasing the morbidity and mortality from this condition.[1-5] Toward this end, Medicare coverage was extended to include triennial Papanicolaou testing beginning in July 1990.[6] Whereas passage of this benefit should solve the problem of financial barriers, several aspects of the clinical implementation of the program remain unresolved. Because uncertainties still exist in our knowledge about cervical cancer, there is no consensus approach to the screening, diagnosis, and treatment of cervical neoplasia, particularly for elderly women.

This article reviews the controversial and uncertain aspects of the natural history of cervical cancer in elderly women to provide clinicians with the background necessary for informed assessment of screening recommendations and integration of new data, as they become available, into practice. For the review, published studies from 1950 to 1988 were examined with the use of a standard abstraction form summarizing location, methods, quality of the data, and the applicability of the findings to older women.

We examined factors that may affect the usefulness of screening in the elderly, including the following: (1) how quickly the disease progresses from cervical intraepithelial neoplasia (defined as cervical intraepithelial neoplasia grade 1 or mild dysplasia and cervical intraepithelial neoplasia grade 2 or moderate dysplasia) to carcinoma in situ (defined as cervical intraepithelial neoplasia grade 3 or severe dysplasia and carcinoma

in situ), and finally to frankly invasive carcinoma (expressed by the duration in each state); (2) what proportion of preinvasive disease develops into invasive cancer in elderly women; (3) Papanicolaou test characteristics; (4) hysterectomy status; and (5) cohort and subgroup risks.

Disease state duration

The goal of screening for cervical cancer is to diagnose and treat cervical cancer in its early, preinvasive states, such as cervical intraepithelial neoplasia and carcinoma in situ, when survival is close to 100%. If these preinvasive states have a long duration, say 10 years, then the clinician can safely screen most women every 3 to 5 years. Alternatively, if the duration of preinvasive disease is as short as 1 or 2 years then screening will need to be performed annually. Thus the disease state duration is a major determinant of the appropriate periodicity of screening.

Unfortunately, there is no consensus about the duration of cervical neoplasia in women of all age groups, and even less agreement about duration in elderly women. Four methods have been used by researchers to estimate the duration of the various states of cervical neoplasia. The first method estimates duration through direct observation of women with disease and followed up without intervention.[7] This method is now considered unethical unless the subjects have been offered treatment and have refused.

A second method of estimating the duration of each state of neoplasia uses the ages at which the largest number of cases occur (the mode or modal age) to infer the time from the start of a state to the start of the next state. For example, if the modal age of carcinoma in situ were 35 years and the modal age for invasive cancer were 50 years, the estimated average duration from the beginning of carcinoma in situ to the beginning of invasive cancer would be estimated as 15 years.

However, a few caveats should be noted that may affect conclusions about the elderly on the basis of the use of this method. First, estimates obtained as a result of subtracting modal or mean ages of incidence only yield a correct estimate if each state being considered can be measured from the identical point in its evolution. Because younger women are most likely to have lesions diagnosed through routine screening, their lesions are detected close to the actual onset of neoplastic changes. Older women, in contrast, who are not routinely targeted in screening programs, are more likely to have lesions diagnosed closer to the end of the neoplastic spectrum, when lesions are more likely to produce symptoms such as vaginal bleeding. In this situation, the use of modal or mean ages to estimate duration will overestimate the true duration from the beginning of a state, such as carcinoma in situ, to the beginning of the next state, invasive cancer, to the extent that symptomatic cases are represented in the population.

That this method does, in fact, yield overestimates is supported by the observation that carcinoma in situ duration derived in this manner is twice the duration estimated for the same population database with other methods.[8, 9]

In addition, this method may obscure cohort differences because data used are generally cross-sectional.[9] When cohort risk varies from generation to generation, prediction of disease duration from data on previous generations may not be accurate for current or future groups of elderly women. Despite these cautions, this technique has been widely used because it is simple and uses readily available data.

A third method to assess duration uses the method described by MacMahon et al.[10] in which the average duration of a disease, from onset to termination, is a ratio of prevalence to incidence in a given time period. Dunn[11] and Kashgarian and Dunn[12] draw on this relationship and concluded that older women and black women have shorter durations of carcinoma in situ than do women in general. For white women, they estimated carcinoma in situ duration to be 5 to 16 years for women under age 65 years and only 1 year for women age 65 and older. However, it should be noted that the estimates are made on the basis of the results of Papanicolaou smears obtained from samples in which women aged 20 to 39 years were overrepresented and women 55 to 74 years were underrepresented.

In addition, the accuracy of estimates with the use of incidence and prevalent cases defined by Papanicolaou smear results will be reduced by misclassification errors. Also, the estimates will be correct only if the incidence and prevalence rates are constant over the time period of measurement and if both are measured from the same state in the disease process, as noted above. If prevalence rates are increasing or if screening rates differ, the estimates can also be distorted. Although age-specific rates are incorporated into the estimates from the large-population screening program used by Kashgarian and Dunn,[12] the estimates of duration may also have a wide range of error when applied to older women as a result of small numbers of elderly being screened. Last, these estimates assume similar mortality rates for women at all ages. For elderly women, who have higher mortality rates than younger women, this assumption may underestimate the true duration of cervical neoplasia. Despite the potential limits, other researchers using similar methods and different data sets have derived comparable estimates of duration.[9, 13]

A fourth method, mathematical modeling, is used to estimate both the duration of different disease states and the proportion of lesions in each state that pro-

gresses to the next state. One such technique is Markov modeling, which simulates the progress of a population through various disease states.[14] Markov models are homogeneous when the probability of moving between states is kept constant over time, or nonhomogeneous when the transition probabilities are allowed to depend on time or age.

Richart and Barron[15-18] used a homogeneous Markov process to assess the duration of cervical intraepithelial neoplasia in two quite different data sets and derived similar results from each.[15-18] They concluded that the duration of cervical intraepithelial neoplasia was independent of age, that is, that it was constant across different age groups. It should be noted that whereas the data they used for their estimates were very reliable, the estimates were made on the basis of cervical intraepithelial neoplasia rates in women aged 20 to 39 years.

Coppleson and Brown[19] attempted to show that the results based on age-independence for carcinoma in situ did not fit the observed data. They used data collected by Bibbo et al.[20] in a nonhomogeneous (age-dependent) Markov model for their estimates. In the large series reported by Bibbo et al. 12% were over 49 years old; there is no information on the actual age distribution. Coppleson and Brown assumed these older women to be age 65 for their model. From the estimates of the duration of carcinoma in situ derived from their models they concluded that duration of cervical neoplasia in elderly women was one quarter that of younger women. However, the assumption that women over 49 years old are age 65 may invalidate their conclusions for women aged 50 years and older and probably underestimates the transition times of older women. Also, estimates obtained as a result of this type of data pooling may lack precision. Hence, whereas it may be true that an age-independent model does not fully explain the observed natural history of the disease, the Coppleson and Brown analysis does not resolve the issue.

Table I summarizes the estimates of carcinoma in situ duration from studies with both age-dependent and age-independent models. The median estimate of carcinoma in situ duration derived with age-independent models is 9.5 years for all ages, compared with the age-dependent models, which estimate 16 years for younger women, 4 years for women aged 50 years or older, and 1 year for women aged 65 years and older. Therefore the duration of carcinoma in situ in the elderly may be as long as 9 years or as short as 1 year.

The new Medicare benefit for Papanicolaou testing covers screening at 3-year intervals. The choice of this interval is influenced by the need to provide the most benefit per dollar spent for the overall population of elderly women.[21] From the clinical perspective, triennial screening should be adequate to detect most disease in preinvasive states. However, if preinvasive cervical cancer states have a shorter duration in older women, as compared with younger women, recommended screening intervals may need to be adjusted. Future cohort studies that focus on older women may provide the information needed to resolve this issue.

Probability of progression and regression of each state

To determine the most appropriate diagnostic and treatment course for an elderly woman with abnormal Papanicolaou smear findings, the clinician will also need to know the likelihood that a given lesion will progress to a more severe state. If a lesion is certain to progress to invasive carcinoma, an aggressive work-up is warranted. But, if a lesion is more likely to regress to a less severe state or remain static, conservative management could be considered.

Unfortunately, the probability of remaining in a given state, progressing to the next state, or regression to the prior state is as difficult to determine as durations, particularly for the elderly. The best estimates of disease behavior are made on the basis of groups of women with cervical intraepithelial neoplasia and carcinoma in situ who were followed up without intervention. Because it is unethical to follow up women without treating them once carcinoma in situ develops, the probability of progression from carcinoma in situ to invasive cancer is even more difficult to assess than that for progression from cervical intraepithelial neoplasia to carcinoma in situ.

On the basis of a longitudinal follow-up study of untreated cervical intraepithelial neoplasia, Barron and Richart,[17] estimated that after 10 years 66% of all cervical intraepithelial neoplasia lesions will progress to carcinoma in situ, 28% will remain in cervical intraepithelial neoplasia, and 6% will revert to normal. Regression to normal occurred only from very mild or mild cervical intraepithelial neoplasia.

In contrast, Fox[22] followed up 278 women with cervical intraepithelial neoplasia and noted that 31% of lesions regressed to normal, 9% remained in cervical intraepithelial neoplasia, and 60% progressed to carcinoma in situ. Several women regressed after termination of pregnancy or completion of antiinfection treatment, but in 13% of the women whose smears originally regressed to normal cervical intraepithelial neoplasia subsequently developed. The redevelopment of cervical intraepithelial neoplasia after regression to normal has been noted in other series.[23, 24] In fact, in one of these series, among women over age 45 years (ages 45 to 65) whose initial cervical intraepithelial neoplasia lesions regressed, 40% subsequently recurred per year.[24] All these findings suggest that misclassification biases have resulted in overestimates of the regression rate of cervical intraepithelial neoplasia.

Estimates of the probability of regression from cer-

Table I. Duration of cervical neoplasia

Study	*Year*	*Study type*	*Study population*	*Age group (yr)*	*CIS duration (yr)*	*Age relationship*	*Method of estimation*
Canadian Task Force	1976	Cross-sectional	Canadian women; included 12% of elderly population	All ages	9.7-13.4	Independent	Mean age
Fidler et al.	1968	Cross-sectional	12% of elderly women	All ages	6-9.5	Independent	Prev/incid = duration
				All ages	12	Independent	Mean age
Peterson	1956	Longitudinal	212 Danish women referred for specialty care from 1930-1950; a few over 40	All ages	3.7 (range, 0.4-8.8)	Independent	Direct observer
Barron et al.	1978	Cross-sectional	Data from women in Barbados and British Columbia	All ages	3-10	Independent	Prev/incid = duration
Coppleson, Brown	1975	Cross-sectional	Data from women attending family planning clinics, and national data from the Third National Cancer survey	<50	17	Dependent	Markov model
				≥50	4	Dependent	Markov model
Kashkargian, Dunn	1970	Cross-sectional	>110,000 women in Memphis, 2%	25-35	16	Dependent (using age-specific data)	Prev/incid = duration
				40-50	5	Dependent (using age-specific data)	Prev/incid = duration
				>65	1	Dependent (using age-specific data)	Prev/incid = duration

CIS, Carcinoma in situ; *prev*, prevalence; *incid*, incidence.

vical intraepithelial neoplasia to normal have also been derived from studies in which lesions have been diagnosed through biopsy specimens. The proportion of cervical intraepithelial neoplasia lesions observed regressing to normal in these settings ranges from 20%[25] to 47%.[26] The lower rates of regression noted in nonbiopsy specimen studies compared with the biopsy specimen studies cited above suggests that the act of establishing the diagnosis altered the results.[15]

Estimates of the regression of carcinoma in situ range between zero[7] and 25%.[22] In one series in which women with carcinoma in situ were followed up without treatment (as a result of refusing treatment or loss to follow-up), no regression was noted among women age 40 years and older, whereas 32% of carcinoma in situ cases regressed among women under age 40.[27] Coppleson and Brown,[19] with the use of a data set that included women over the age of 45 years, concluded that the probability of disease progression from carcinoma in situ to invasive cancer rises with increasing age. A lower regression rate of cervical intraepithelial neoplasia has also been observed among older women compared with younger women.[24]

Whereas these conclusions are consistent with clinical observation, it is also possible that the apparent increased likelihood of progression with increasing age is an artifact of cross-sectional data in conjunction with historically low screening rates for older women. Nonetheless, a higher probability of disease progression is biologically plausible: the elderly have been noted to have decreased immune response compared with younger populations and immunosuppressed women in a variety of settings have been noted to have high rates of cervical neoplasia[28, 29]; in addition, changes in the hormonal environment with menopause have been proposed as promoters of neoplasia.

Given the current state of our knowledge of the behavior of cervical neoplasia, most groups recommend that elderly women with abnormal Papanicolaou smear findings receive a thorough colposcopic examination and, if the transformation is not fully visualized, a cone biopsy should be performed.[21] New techniques may also become available, such as cervigrams, which may be helpful in guiding the treatment of elderly women.[30]

In addition, as the implications of the presence of human papillomavirus (HPV) in cervical neoplastic lesions is more fully understood, simultaneous Papanicolaou and HPV testing holds the promise of guiding treatment protocols. In one study of HPV and cervical intraepithelial neoplasia, Campion et al.[31] noted that 90% of cervical intraepithelial neoplasia grade 1 lesions positive for HPV type 16 progressed to cervical intraepithelial neoplasia grade 3 in an average of 22.4 months. Moreover, only 7% of cervical intraepithelial neoplasia lesions regressed and none of these contained HPV type 16. This study, based on a small, selected sample of young women in a referral colposcopy clinic, needs to be confirmed in other populations and other age groups before recommending guidelines on the basis of HPV status.

Also, there are no data yet on HPV infections in elderly women in this country. The only U.S. study of HPV in older women of which we are aware is a description of HPV in hysterectomy specimens, where surgery was performed for nonmalignant conditions.[32]

In Germany, deVilliers et al.[33] examined more than 9000 women for HPV types 16/18 and 6/11; 10% of the study sample were aged 60 years or older.[33] They found that the association between HPV and cervical intraepithelial neoplasia, and HPV and normal smears, generally decreased with age, although there is some suggestion from their data that the age-specific distribution of HPV in cervical intraepithelial neoplasia lesions is bimodal, with the second peak at about age 75 years. Of note was their finding that among women with invasive cancer, HPV was present more often in elderly women than in younger women. This observation supports the hypothesis that age-related changes may interact with the neoplastic process.

Papanicolaou test characteristics in the elderly

Accuracy of the Papanicolaou test at all ages is crucial if the smear is to perform effectively as a screening test. The accuracy of the Papanicolaou test has two basic components: the sampling component and the evaluation component. Each of these includes both avoidable errors (e.g., inadequate sampling or errors in reading a slide) and unavoidable errors (e.g., because of the biologic characteristics of the lesion) that prevent Papanicolaou smear accuracy from being 100% in any age group. In addition, several characteristics of the elderly patient may influence the accuracy of the Papanicolaou smear; these include anatomic changes associated with aging, particularly decreased accessibility of the squamocolumnar junction.

Cervical cancer arises at the junction of the squamous epithelium of the vagina and the columnar epithelium of the endocervix.[34] The area where these two meet is referred to as the squamocolumnar junction, which must be sampled for accurate Papanicolaou testing. The location of this junction varies with age. In younger women it is located at the external cervical os, moving onto the exocervix after childbearing, and then back into the endocervical canal after menopause.[35]

Movement of the squamocolumnar junction higher into the cervical canal with increasing age renders this area less accessible for sampling. In addition, failure of exfoliation of abnormal cells is more likely in postmenopausal women than in younger women.[36] Moreover, vaginal and cervical os stenosis may hinder sampling.

A study by Roberts et al.[37] shows some of these potential pitfalls in examining older women. In this series, 50 postmenopausal women with negative Papanicolaou smear results underwent colposcopy. Eleven women had positive results, four (8%) of these being cervical intraepithelial neoplasia.[37] The discrepancy between the Papanicolaou test and the colposcopy observed in this study was ascribed to diminished exfoliation of cells and anatomic inaccessibility of the transformation zone to sampling in older women. Although this was not a random sample of older women, the finding of a high rate of false-negative smears is consistent with the anatomic changes seen in this age group.

In addition to clinical sampling errors, evaluation errors may also affect the accuracy of the test. Evaluation errors may lead to false-negative results when abnormal cells are missed and to false-positive results when normal cells are identified as abnormal. In general, false-negative rates vary with age, study, and setting, and the state of the lesion, and have been reported to range from 5% to 35%,[15, 38-42] although most of these rates were obtained in populations of women whose average age was 35 years.

There is a similar paucity of primary data on the false-positive rate of cervical smears among elderly women. In general, false-positive rates described for nonelderly women have ranged from less than 1% to 5%.[21, 38, 41, 43] In two recent reports of Papanicolaou screening of elderly women false-positive rates of 0.1%[44] and 0.3%[45] occurred. The clinician should be particularly alert to atrophic smears because the normal atrophic changes that occur in postmenopausal women can result in vulnerability to inflammation and injury and these responses can mimic varying degrees of neoplasia.[44, 46, 47] Koss[47] discusses these and other pitfalls of cervical cancer screening in his recent review of Papanicolaou testing.

The recent guidelines for classification of Papani-

colaou smears recommended by the National Cancer Institute Workshop (Bethesda system)[48] addresses many of the potential problems in Papanicolaou screening for the elderly. The Bethesda system recommends that Papanicolaou smear reports comment on the adequacy of the specimen, provide a general categorization of the results as either normal or other, and contain a descriptive diagnosis. If a specimen does not contain endocervical components the smear should be repeated. The descriptive diagnoses used in the Bethesda system should allow the clinician to distinguish between infection and reactive-reparative changes and epithelial cell abnormalities. This descriptive system also incorporates a recommendation for further evaluation. Thus the cytopathologist will play an integral role in assuring that specimens from elderly women are properly obtained, interpreted, and followed up.

Other parameters

Other parameters that the clinician should consider that may influence the yield of screening programs for aged women include hysterectomy prevalence and cohort effects.

Hysterectomy status. Older women who had hysterectomies should not automatically be excluded from screening programs. Before the early 1960s many women had partial hysterectomies that left the cervix intact. In one study, one third of the elderly women with a history of a hysterectomy had an intact cervix on clinical examination.[44] Between 4% and 8% of cervical cancer arises in these cervical stumps.[49, 50] Also, women who had a hysterectomy for malignant disease have a high risk of subsequent development of vaginal cancer.[51] Therefore a careful history including the date of surgery, type of operation performed, and indications for the hysterectomy is important in determining which older women should continue to receive Papanicolaou smears. Often an initial speculum examination is also necessary to verify the patient's status. In the future, the majority of women with a history of a hysterectomy are likely to have had surgeries that removed the cervix. At that point, the reason for the prior surgery will be the best guide to the need for continued Papanicolaou surveillance.

Cohort effects. Several authors have noted variations in cohort incidence and mortality rates.[52, 53] The implications of such cohort trends for clinical practice are not clear and many questions remain with regard to current and future cohorts of women: is the current cohort of elderly women, who were generally beyond their reproductive years when Papanicolaou screening was beginning to be widely used, only at risk because of a lack of prior regular screening; will future cohorts of elderly women, who will have had more extensive screening as younger women, continue to need surveillance; will HPV infection increase risk of future groups of women; will different subgroups within age cohorts, such as poor and minority women, continue to be at higher risk than nonpoor, white women? It behooves physicians to research these issues and ensure that new data are incorporated into screening recommendations in a timely manner.

The answers to these questions also have important implications for clinical practice. Cervical cancer screening in the elderly will be most effective if providers concentrate on screening those women, who, by virtue of socioeconomic status, race, or other personal characteristics or history, are at highest risk of development of neoplasia. Obviously, women who have never been screened should also receive priority for initial screening and outreach activities.

Comment

Despite aggressive screening and declines in cervical cancer mortality in the United States over the past four decades, between 1973 to 1974 and 1985 to 1986 mortality rates declined only 17% among women aged 50 years and older, compared with 43% for women under age 50, with rates in older black women persisting at nearly triple the rates in older white women.[54] Women aged 65 years and older continue to account for nearly one half these cervical cancer deaths.[55]

One of the most common reasons why women with invasive cervical cancer have not been detected at earlier stages, when treatment yields survival rates of 80% to 99%, is that they have never been screened.[56-61] This has been particularly true for elderly women.[57, 59, 61] The extension of Medicare coverage to cervical cancer screening will expand access to Papanicolaou testing to the growing elderly segment of our population and holds the potential, particularly for high-risk women such as the poor and racial minorities, to eliminate the avoidable morbidity and mortality from cervical cancer in this country.

We thank Elaine Power, Brigitte Duffy, and Judith Wagner for assistance with the Office of Technology Assessment Report, Evonne Doran-Brown and Barbara Kennedy for their support, and Dr. Harry Rubin and Dr. Kurt Deuschle for support of earlier versions of this work.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Toxicities in rats with free versus liposomal encapsulated cisplatin

Ronald K. Potkul, MD,[a] Javed Gondal, PhD,[b] Pincas Bitterman, MD,[c] Kenneth L. Dretchen, PhD,[d] and Aquilur Rahman, PhD[b]

Washington, D.C.

Wistar rats (five in each group) were given either 1 mg/kg of free cisplatin, 1 or 2 mg/kg of liposomal encapsulated cisplatin, or saline solution intraperitoneally biweekly for 15 injections. Rats in the free drug group showed significantly less weight gain; two rats died during the study. At necropsy, the free cisplatin–treated rats showed gross and microscopic evidence of peritoneal fibrosis that was not detected in any of the remaining groups. The free cisplatin–treated rats showed serum and histologic evidence of renal damage; all five rats had moderate or severe acute tubular necrosis. No renal abnormalities were detected in rats that received 1 mg/kg, and only focal or mild changes were found in rats that received 2 mg/kg of the liposomal preparation. Neurotoxicity, as determined by nerve conduction and inclined plane studies, developed in rats treated with free and liposomal cisplatin. These results are encouraging and warrant further investigation. (Am J Obstet Gynecol 1991;164:652-8.)

Key words: Cisplatin, liposomes, intraperitoneal chemotherapy

Ovarian cancer is the leading cause of death from gynecologic malignancies in the United States. It is estimated that there will be 20,500 new cases of ovarian cancer in 1990, which will eventually cause 12,400 deaths.[1] During the past 15 years, a major research effort has focused on ovarian cancer. Cisplatin (*SP*-4-2, diamminedichloroplatinum) has shown extensive activity against ovarian tumors, both alone and in combination with other agents. Initial response rates as high as 79% and 98% with cisplatin-containing regimens[2, 3] most patients are not cured of disease, and further improvements in therapy are necessary.

Several studies have suggested a clinically important dose-response relationship with cisplatin. Bruckner et al.[4] and Ozols et al.[5] gave high-dose cisplatin (120 and 200 mg/m^2, respectively) to patients who no longer had response to low-dose cisplatin therapy or who had a recurrence and responses were observed. Although high-dose cisplatin was particularly effective in patients who previously had responses, responses were also observed in patients who had stable disease or progressive disease while they received conventional doses of the chemotherapeutic agent. Unfortunately, the renal toxicity and neurotoxicity of intravenous high-dose cisplatin was substantial. Thirty-two percent of the patients in the study of Ozols et al.[5] had a rise in serum creatinine level (mean 2.1 to 5.6 mg/dl). In 37% of the patients severe paresthesia developed and two of those 19 became wheelchair dependent, which limited the clinical usefulness of these dose escalations.

An alternate approach that takes advantage of the apparent dose-response relationship to cisplatin is intraperitoneal chemotherapy. Studies with intraperitoneal cisplatin have demonstrated a pharmacologic advantage (peak peritoneal level to plasma level) of 21 to 72 mg/dl.[6, 7] The ability to provide locally high concentrations of cisplatin to tumor cells is dependent on good drug distribution in the peritoneal cavity. Unfortunately, a chemically induced peritoneal sclerosis by cisplatin has limited the number of intraperitoneal cycles that can be administered.[8]

There is a growing body of preclinical and clinical evidence suggesting that the liposomal encapsulation of chemotherapeutic agents can decrease toxicity while antitumor activity is retained.[9-12] We have recently encapsulated cisplatin in our laboratory, and a preliminary study of the short-term exposure to the drug in rats demonstrated significantly less nephrotoxicity with no loss in therapeutic efficacy in the L1210 leukemia and NIHOVCAR human cell lines (unpublished data). The nephrotoxicity (blood urea nitrogen and creatinine evaluations) of liposomal cisplatin in rats that received

6/1/25358

6 mg/kg intravenously was significantly less than that observed with cisplatin (66 versus 172 and 1.2 versus 2.2 mg/dl for blood urea nitrogen and creatinine, respectively). The current study was undertaken to evaluate the nephrotoxicity, neurotoxicity, and peritoneal toxicity of long-term exposure of free and liposomal encapsulated cisplatin in rats when it is administered intraperitoneally.

Material and methods

Animals. Female Wistar rats, 11 to 13 weeks old, weighing 175 to 200 gm, were purchased from Charles River Breeding Laboratories, Inc. (Boston). All animals were maintained according to accredited procedures at the Georgetown University animal facility with institutional Georgetown University Animal Care and Use Committee approval, and were fed Purina Rat Chow (Ralston-Purina Co., St. Louis) and water as desired.

Liposomal preparation. Cisplatin was provided by the Biological Testing Branch, Developmental Therapeutic Program, Division of Cancer Treatment, National Cancer Institute, Bethesda. Phosphatidylcholine, phosphatidylserine and cholesterol were purchased from Sigma Chemical Co., St. Louis. Phosphatidylcholine, phosphatidylserine, and cholesterol in a 3:3.1:3.7 molar ratio were dissolved in chloroform/methanol (5:1 vol/vol), after which the organic solvents were evaporated in a rotating flask under a vacuum. Of all the lipids used, these lipids in the ratios cited produced the highest encapsulation of cisplatin (35% to 45%). Cisplatin (3 mg/ml) in a hydration buffer solution (0.25% sodium chloride and 5% mannitol) was added to the film of dried lipids and dispersed by sonication (Mettler Instrument Corp., Hightstown, N.J.) for 10 minutes, purged with nitrogen, and left overnight in a ground neck flask for hydration. The hydrated suspension was sonicated for 20 minutes at 37° C at output control No. 7 in a Cuphorn sonicator (model 380, Heat Systems Ultrasonics, Inc., Farmingdale, N.Y.) to form liposomes. The liposome suspensions were dialyzed against saline solution for 3 hours (three changes, 1 hour each) at room temperature to remove the unencapsulated cisplatin. The remaining platinum encapsulated within liposomes was measured with atomic absorption spectrophotometry as described previously.[13] Stability studies demonstrate a shelf life for the preparation of at least 2 weeks at 4° C.

Drug treatment. Cisplatin was dissolved in saline solution to a final concentration of 0.04 mg/ml for a 1 mg/kg body weight dose, and liposomal cisplatin was suspended in saline solution to final concentrations of 0.04 and 0.08 mg/ml for 1 and 2 mg/kg doses, respectively (volume of injection 2.5 ml/100 gm, 2.5% body weight). Female rats (five in each group) were treated with 1 mg/kg cisplatin and both 1 and 2 mg/kg liposomal cisplatin intraperitoneally biweekly for 7½ weeks for a total of 15 injections. Drug treatment was withheld if the rat showed signs of severe toxicity. Five control rats received saline solution alone. The rats were put to death at week 10. To reduce renal toxicity a chlorouresis was induced in all groups by pretreatment with subcutaneous furosemide (12.5 mg/kg).[14]

Neurotoxicity. Noninvasive nerve conduction studies were performed at weeks 9 and 10 according to the technique described by DeKoning et al.[15] Briefly, the rats were anesthetized with ketamine and 2% xylazine (50 mg/kg). The tibial nerves were stimulated at the ankle by a 0.1 msec square-wave pulse delivered by a stimulator (Grass Instrument Co., Quincy, Mass.). The M and H responses were recorded from the small muscles on the plantar surface of the hind foot by a surface-recording electrode on a digital storage scope. The M response occurs in reaction to stimulation of the α-motor fibers, whereas the H response reflects stimulation of the afferent proprioceptic Ia fibers, which in the spinal cord monosynaptically excite α-motor neurons. The animals were also tested on an inclined plane by placing them on a board that could be elevated slowly.[16] The mean angle at which the rat failed to remain on the plane was determined by five independent trials.

Serum and histologic evaluation. At week 10 blood was obtained by cardiac puncture into 5 ml tubes, and serum was separated by centrifugation in a centrifuge (Beckman Instruments, Inc., Fullerton, Calif.) at 1800 *g* for 20 minutes. Standard serum chemistries were performed by the Georgetown Hospital Clinical Chemistry Laboratory with a Hitachi 737 automatic analyzer (Boehrman and Mannheim Diagnostics, Indianapolis). At necropsy, the liver, kidneys, intestine, and sciatic nerve were harvested, fixed in 10% buffered formaldehyde, and embedded in paraffin; sections were routinely stained with hematoxylin and eosin and evaluated microscopically in a blinded manner by one of us (P.B.). The nerves were stained with Luxol (DuPont Co., Wilmington, Del.) fast blue. Acute tubular necrosis was diagnosed if dilated tubules, lined by flattened epithelium showing atypical nuclei and mitotic figures and hyaline casts, were present. Acute tubular necrosis was graded as mild (focal) if <10% of the kidney sections showed the above morphologic changes, moderate if >10% of the kidney sections but <25% showed morphologic changes, and severe if >25% of the sections showed necrotic changes. The liver and intestine peritoneal surfaces were evaluated for significant pathologic changes that included inflammation and fibrosis.

Statistical analysis. Statistical analysis was performed with the two-tailed Student *t* test with significance defined as $p < 0.01$. Nonparametric analysis was done by χ^2.

Table I. Renal function tests in rats receiving long-term treatment with free or liposomal encapsulated cisplatin

Group	*Blood urea nitrogen*	*Creatinine*	*Potassium*	*Uric acid*	*Phosphorus*
Free cisplatin (1 mg/kg)	16.7 ± 1.5	0.6 ± 0.1	9.1 ± 0.7*	3.1 ± 0.7*	11.1 ± 1.2*
Liposomal cisplatin					
1 mg/kg	18.8 ± 1.5	0.7 ± 0.04	5.0 ± 0.5	1.1 ± 0.3	7.7 ± 0.9
2 mg/kg	16.2 ± 2.9	0.7 ± 0.2	5.6 ± 0.8	1.0 ± 0.4	8.6 ± 0.6

Results

General toxicity and weight changes. Rats in the cisplatin-treated group showed significantly less weight gain during the course of the study. Their average weight gain was 15 gm, as compared with 83, 69, and 63 gm for the control, 1 mg/kg liposomal cisplatin, and 2 mg/kg liposomal cisplatin groups, respectively ($p < 0.01$). Two of the five free cisplatin-treated rats appeared very ill during the study; less body fat and ascites necessitated withholding treatment at weeks 6 and 7. These two rats died during the study at weeks 7 and 9. None of the rats in the control or liposomal cisplatin–treated groups appeared ill, developed ascites, or died during the study period.

Clinical chemistry. At the end of the experiment serum was obtained from the 18 surviving rats. Evidence for nephrotoxicity with significantly elevated ($p < 0.01$) serum potassium, uric acid, and phosphorus levels was found in the rats given free cisplatin (Table I). These chemistry results were 9.1 mEq/L, 3.1 mg/dl, and 11.1 mg/dl as compared with 6.1 mEq/L, 1.2 mg/dl, and 9.0 mg/dl in the saline solution–treated rats. These values in the liposomal cisplatin groups were not significantly different from those in the saline solution controls. The mean serum concentrations of glucose, blood urea nitrogen, creatinine, bilirubin, total protein, triglycerides, cholesterol, sodium, serum glutamic pyruvic transaminase, serum glutamic oxaloacetic transaminase, lactic dehydrogenase, calcium, chloride, and bicarbonate were not different among the four different treatment groups.

Gross findings. At necropsy, three of the five rats in the cisplatin-treated group showed extensive serosal fibrosis of the peritoneal organs that precluded their identification (Fig. 1). A fourth rat demonstrated early fibrosis with thickening of the bowel serosal surfaces. The fifth free cisplatin–treated rat had no gross evidence of peritoneal fibrosis. There was no gross evidence of peritoneal fibrosis in either the control or the liposomal cisplatin groups (Fig. 2).

Microscopic histopathologic evaluations. The bowel disclosed extensive serosal fibrous adhesions in the cisplatin-treated rats. The hepatic capsule showed severe fibrous thickening in four of five rats (Fig. 3) and mild to moderate fibrous thickening in the remaining rat. No fibrosis was seen in any of the liposomal cisplatin treatment groups.

Acute tubular necrosis, which was characterized by dilated tubules that were lined by flattened epithelium showing occasional atypical nuclei and mitotic figures and some hyaline casts, represented the cardinal morphologic findings in the kidney. These morphologic features was produced by the administration of free cisplatin. Data on the incidence and severity of renal lesions are summarized in Table II. Moderate to severe acute tubular necrosis was observed in the kidneys from all five animals that were given free cisplatin (Fig. 4). In contrast, no abnormalities were found in any of the kidneys of the five rats treated with the equivalent dose (1 mg/kg) of the liposomal preparation. Doubling the dose of liposomal cisplatin (2 mg/kg) caused only focal or mild acute tubular necrosis in four of five rats. The fifth rat had no detectable abnormalities. The difference between the acute tubular necrosis scores in the groups given free and liposomal cisplatin was significant ($p < 0.05$).

No evidence of axonal degeneration or myelin breakdown could be detected in any of the study groups.

Neurotoxicity. Data on the mean H response and inclined plane are summarized in Table III. Both 1 and 2 weeks after completion of the 7½-week-drug regimen, the rats underwent neurologic testing by nerve conduction experiments and the inclined plane. At week 9 both the 1 mg/kg free group (three surviving rats) and the 1 mg/kg liposomal cisplatin group had significant slowing of nerve conduction. This improved rapidly and equaled that of the control group at week 10. In spite of this apparent improvement, the inclined plane experiment continued to be significantly abnormal. Unfortunately, because of equipment failure, the 2 mg/kg liposomal cisplatin group could not be tested at week 9, but the H response continued to be signif-

Fig. 1. Severe serosal fibrosis in a rat that received 1 mg/kg free cisplatin.

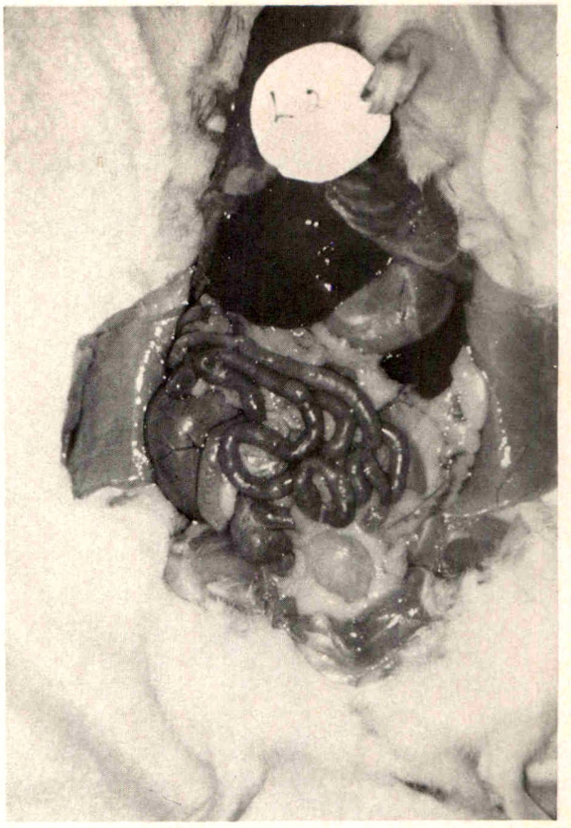

Fig. 2. No evidence of peritoneal fibrosis in a rat that received 2 mg/kg liposomal cisplatin.

icantly prolonged as compared with that of the other groups at week 10.

Comment

Drug carriers such as liposomes have been advocated as a potential means of ameliorating the toxicity of chemotherapeutic agents. This concept has been extensively studied in our laboratory by use of liposomal encapsulated doxorubicin and vincristine. In experiments that used a mouse model, liposomal doxorubicin was found to exert activity at doses that caused fewer myocardial alterations than did the same doses of free doxorubicin.[9] These findings were confirmed in a study of chronically administered doxorubicin in beagles and in a phase I clinical trial in which no cardiac toxicity was encountered, even at very high cumulative doses of the liposomal encapsulated drug.[10, 11] A similar decrease in toxicity is apparent in a liposomal preparation of vincristine.[12] In the mouse model, 3 mg/kg of free drug is lethal in 90% of the animals. A 7.5 mg/kg dose of liposomal vincristine was lethal in only 10% of the mice. Concurrently, we observed a significant improvement in the therapeutic efficacy of the liposomal preparation against L1210 leukemia as compared with the efficacy of the free drug at equal doses.

The difference in renal tissue damage induced by free and liposomal cisplatin was striking. In all of the animals receiving free cisplatin, moderate or severe acute tubular necrosis developed; this has been well documented in rats that received the free drug.[14] The effects of cisplatin in these animals are similar to the cardinal features induced in humans who receive cisplatin, namely, focal acute tubular necrosis, casts, dilated tubules, and epithelial atypia.[17] There was no evidence of acute tubular necrosis in rats that received the equal dose (1 mg/kg) of the liposomal preparation, and, in fact, only very minimal signs of acute tubular necrosis were found in the rats that received twice the dose (2 mg/kg). The serum chemistry results were somewhat confusing. Although the rats that received free cisplatin had significantly elevated uric acid, potassium, and phosphorus levels that were consistent with chronic renal insufficiency, blood urea nitrogen and creatinine levels were not significantly elevated. These rats appeared malnourished, with loss of body fat and muscle mass that could explain the normal cre-

atinine despite acute tubular necrosis. The extensive peritoneal sclerosis may have limited food (i.e., protein) intake, thus lowering the serum blood urea nitrogen level in the animals with renal insufficiency.

A reduction in renal toxicity would be expected to be associated with other signs of protection, such as a decrease in the incidence of renal-related deaths. These factors were not directly addressed in the present study, but it should be noted that two of five rats that received free cisplatin (1 mg/kg) died, whereas all rats that received liposomal cisplatin (both 1 and 2 mg/kg) survived until the experiment was ended.

Liposomal encapsulation provided a means of altering other types of platinum toxicity. In this study peritoneal fibrosis developed in all rats that received free cisplatin intraperitoneally and obliterated the peritoneal cavity in three of five rats. Fibrosis was undetectable both grossly and histologically, even in the rats that received the high dose (2 mg/kg) of the liposomal preparation. We have previously shown in a phase I trial that doxorubicin can be safely administered intraperitoneally at significantly higher doses when it is encapsulated in liposomes.[18] Ozols et al.[19] encountered unacceptable chemical peritonitis with the administration of 15 to 20 μg/ml of free doxorubicin. We did not find this dose limiting toxicity with even 50 μg/ml of the

liposomal encapsulated drug. Peritoneal chemotherapy with its high peritoneal/serum ratio has many theoretical benefits. A large randomized phase III protocol (Southwest Oncology Group and Gynecologic Oncology Group) is attempting to answer the question of an actual clinical benefit of intraperitoneal versus intravenous cisplatin. If superiority of intraperitoneal administration is determined, this lack of fibrosis could have major clinical benefits by not limiting the number of intraperitoneal cycles that can be adequately delivered to the patient.

Damage to the sensory nerves that results in decreased conduction velocity and in sensory neuropathy has been reported in rats and humans who receive cisplatin.[15-20] The pathologic changes in peripheral nerves are most marked distally, which can explain the lack of abnormalities in the sciatic nerves of rats with severe neuropathy. Our comparative evaluation did not show a decrease in neurotoxicity with the liposomal encapsulated drug as compared with the free drug. However, using the same model system we have demonstrated a neuroprotective effect of the liposomal encapsulation of vincristine. The H responses were 5.5, 6.4, and 5.7 msec for the saline solution, free, and liposomal vincristine groups, respectively.[12] A larger experiment that more specifically examines dose-effect threshold and nerve recovery may show a difference between free and liposomal cisplatin.

In conclusion, the results of this study show that long-term intraperitoneal cisplatin-induced renal toxicity and peritoneal fibrosis can be markedly reduced by the administration of the liposomal preparation of this agent. Although these results are exciting, a detailed study is warranted to evaluate the role of liposomal cisplatin in the potential decrease of neurotoxicity associated with this important agent. The preliminary data indicate that this modality of treatment may have significant application in a clinical setting, and we believe that additional studies are warranted.

We thank Margaret Everett for her assistance in the preparation of this manuscript.

Cocaine in pregnancy: The effect of maternal administration of cocaine on the maternal and fetal pituitary-adrenal axes

J.R. Owiny, PhD, M.T. Jones, PhD, D. Sadowsky, T. Myers, A. Massman, MD, and P.W. Nathanielsz, MD, PhD

Ithaca, New York

The effects of cocaine on the maternal and fetal pituitary-adrenal axis in vivo during pregnancy have not been reported. Six pregnant ewes and their fetuses underwent instrumentation at 113 to 119 days' gestation. Ewes were assigned to receive an intravenous bolus injection of vehicle or cocaine (0.5, 1.0, or 2.0 mg · kg^{-1}) at 124 to 136 days' gestation. Maternal arterial blood gases, fetal pH and fetal P_{CO_2} were unchanged after injection of cocaine or vehicle. After administration of 2.0 mg · kg^{-1} cocaine, arterial fetal P_{O_2} fell 3.2 ± 1.72 mm Hg ($p < 0.05$) at +5 minutes, returning to baseline by +15 minutes. Maternal and fetal adrenocorticotropin levels rose within 5 minutes after the highest cocaine dose ($p < 0.05$). There was a significant ($p < 0.05$) increase in maternal cortisol at all doses of cocaine and in fetal cortisol at +15 minutes after the 2.0 mg · kg^{-1}. (Am J Obstet Gynecol 1991;164:658-63.)

Key words: Cocaine, hypoxemia, ACTH, cortisol, sheep

Although cocaine abuse during pregnancy is an important clinical problem, few studies have been conducted to assess the mechanisms whereby short-term administration of cocaine can exert its harmful effects on mother and fetus. Clinically, these effects include increased incidence of premature birth, ruptured maternal intracranial aneurysms, intrauterine growth retardation, and abruptio placentae.[1, 2] Cocaine has been shown to cross the placental barrier in pregnancy.[3] Neonates exposed to cocaine in utero show abnormal behavioral responses, especially reductions in interactive behavior.[1]

Cocaine blocks reuptake of catecholamines at nerve terminals, thereby increasing the level of catecholaminergic activity.[4] Catecholamines have been shown to decrease uterine circulation in pregnant sheep[5] and to lead to fetal hypoxemia.[6] Therefore cocaine may stimulate the fetal pituitary-adrenal axis secondarily to the induced fetal hypoxemia.[7] α-Adrenergic mechanisms may also stimulate arginine vasopressin release centrally,[8] which then acts to release adrenocorticotropin (ACTH) from the pituitary gland. Cocaine may also act more directly on maternal and fetal endocrine systems. In the rat, cocaine has been shown to stimulate ACTH release via a corticotropin-releasing factor–dependent mechanism.[9] These observations are in keeping with a stimulatory effect of cocaine on fetal plasma cortisol concentrations. However, in the fetal sheep inhibition of α-adrenergic receptors increases fetal plasma cortisol concentration threefold.[10]

In the sheep the fetal hypothalamic-pituitary-adrenal axis plays a fundamental role in the maturation of several organ systems, including the lung[11] and the hypothalamic-hypophysial-thyroid axis.[12] Cortisol that is secreted by the fetal adrenal as a result of stimulation by the fetal pituitary increases placental conversion of progesterone to estrogen, which eventually leads to labor and delivery.[13] In both human and nonhuman primates the maternal and fetal adrenals play a slightly different role in the process leading to parturition by providing C19 androgens to the placenta as precursors for estrogen synthesis.[14] In view of the importance of the maternal and fetal pituitary-adrenal axes in these critical processes in late pregnancy, we designed studies in the last third of pregnancy to identify the dose-related effects of cocaine on maternal and fetal secretion of ACTH and cortisol.

Material and methods

Care of animals and surgical procedures. Six Rambouillet-Columbia cross ewes, mated on a single occasion and carrying single fetuses of known gestational age, were used. All animals were weighed three to four days before surgery; mean weight was 68.9 ± 3.03 kg (mean ± SEM; range 60 to 78 kg). Surgery was performed at 113 to 119 days' gestation with animals under halothane anesthesia. Indwelling polyvinyl catheters were inserted into the fetal femoral artery and long pedal vein and into the maternal jugular vein and carotid artery.[7] All fetuses were allowed at least 5 days of recovery before undergoing any experimentation.

Administration of cocaine. Cocaine hydrochloride (Sigma Chemical Co., St. Louis) at 100% purity was used for all experiments. Doses of cocaine (0.5, 1.0, and 2.0 mg · kg^{-1} body weight) or vehicle (0.9% sodium chloride, wt/vol), were randomly assigned to the ewes. Each ewe received one injection of vehicle and one of each cocaine dose. Only one dose of cocaine or vehicle was given to each ewe on a single day. All experiments were conducted between 10 AM and 3 PM. Immediately before injection, cocaine was dissolved in 10 ml physiologic saline solution and administered into the maternal jugular vein over 30 seconds. Maternal and fetal arterial blood samples (3 ml) were taken at −30 and −20 minutes before the injection and at +5, +15, +30 and +60 minutes after the injection. The −30 and −20 values were averaged to provide a baseline value. Blood samples were drawn into cold disposable plastic syringes, immediately transferred to chilled heparinized 13 × 100 mm polypropylene tubes, and centrifuged at 4000 rpm for 5 minutes at 4° C. The plasma was transferred to plastic vials, immediately frozen in liquid nitrogen, and stored at −20° C until assayed. Maternal and fetal erythrocytes were aseptically returned after the last sample.

Analytic methods

ACTH. ACTH was measured by radioimmunoassay in unextracted plasma with a miniaturized version of the kit assay (INC Star, Stillwater, Minn.) previously described.[15] Briefly, 50 μl sample or standard was incubated with antihuman ACTH 1-24 antiserum (50 μl) for 24 hours at 4° C. Radioiodinated ACTH 1-24 (50 μl) was added and incubated for a further 24 hours at 4° C. Goat antirabbit precipitating complex (200 μl) was added and incubated for 20 minutes at room temperature (20° to 22° C). Interassay coefficients of variation for quality control samples containing 28.8 pg · ml^{-1} (fetal pool, $n = 9$) and 42.8 pg · ml^{-1} (maternal pool, $n = 8$) were 12.5% and 8.2%, respectively. Intrassay coefficients of variation for fetal and maternal pools were 6.1% and 3.0%, respectively. The limit of detection of this assay, that is, 90% B/BO, was 5.0 pg · ml^{-1}.

Cortisol. Plasma cortisol was measured (Autopak, Micromedics Systems Inc., Horsham, Pa.) as previously described.[15] Briefly, 20 μl samples were extracted with the methylene dichloride method and assayed in antibody-coated tubes with iodinated histamine-3-cortisol used as ligand. The intraassay coefficients of variation for this assay were 9.0% for maternal pool (mean concentration 68.7 ng · ml^{-1}, $n = 24$) and 10.0% for fetal pool (mean concentration 13.3 ng · ml^{-1}, $n = 10$). The interassay coefficient of variation for the maternal pool was 18.3% (mean concentration 45.5 ng · ml^{-1}, $n = 9$) and 22.6% for the fetal pool (mean concentration 19.5 ng · ml^{-1}, $n = 9$). The range of the standard curve was 0.96 to 64 ng · ml^{-1}. Assay sensitivity, calculated as 95% confidence of B/BO, was 0.96 ng · ml^{-1}.

Blood gases. Arterial blood samples were drawn anaerobically into 1.0 ml heparinized plastic syringes and analyzed for Po_2, Pco_2, and pH at 37° C with an ABL2 blood gas analyzer (Radiometer, Copenhagen).

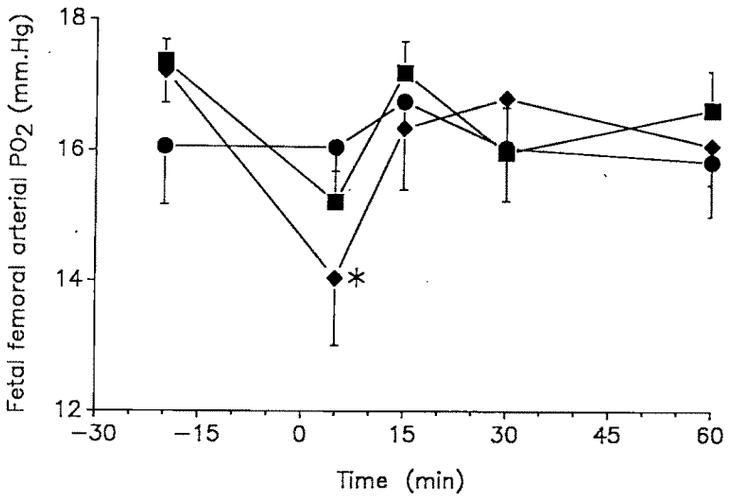

Fig. 1. Fetal femoral arterial P_{O_2} (mean ± SEM, $n = 6$) after injection of vehicle (●) or cocaine 1.0 mg · kg^{-1} (■) or 2.0 mg · kg^{-1} (◆) intravenously to pregnant ewes at 124 to 135 days' gestation. After the 2.0 mg · kg^{-1} dose fetal femoral arterial P_{O_2} at +5 minutes was less than the resting value (*asterisk*, $p < 0.05$).

Statistical analysis. To allow for individual animal variation all data were normalized at each study to the mean of the baseline values for that animal on the day of study. Analysis of variance was performed on each fetal and maternal variable to test for differences with time after injection of vehicle or each dose of cocaine. If initial analysis of variance showed a dose effect, changes within that dose were analyzed for time-related changes with the paired Student t test with Bonferroni correction performed on the normalized data. The level of significance was set at $p < 0.05$. The only significant change at the 0.5 mg · kg^{-1} dose was in the maternal plasma cortisol response. Therefore in the interests of clarity only data from the vehicle and the 1.0 and 2.0 mg · kg^{-1} injections are shown, although the 0.5 mg · kg^{-1} dose was used for the Bonferroni correction. Data throughout are presented as mean ± SEM.

Results

Outcome of experimental preparations. All fetuses were alive and well at the termination of the final cocaine administration. On the final day baseline fetal femoral arterial blood gases were P_{O_2}, 16.6 ± 0.46 mm Hg; P_{CO_2}, 45.5 ± 0.80 mm Hg; and pH, 7.4 ± 0.01. Maternal arterial blood gases were P_{O_2}, 99.3 ± 2.20 mm Hg; P_{CO_2}, 33.2 ± 1.14 mm Hg; and pH 7.5 ± 0.01.

Effect of cocaine on maternal and fetal blood gases

Maternal blood. Baseline maternal carotid arterial P_{O_2}, P_{CO_2}, and pH values did not differ during the study. Within each group maternal P_{O_2}, P_{CO_2}, and pH did not change over time after injection of vehicle or cocaine.

Fetal blood gases. Baseline values for fetal femoral arterial P_{O_2}, P_{CO_2}, and pH did not vary significantly on the 4 days of study. No changes were observed in fetal P_{CO_2} or pH after either vehicle or cocaine administration. There was a rapid transient reduction in fetal P_{O_2} after administration of cocaine, which returned to baseline by +15 minutes (Fig. 1).

Effect of cocaine on maternal plasma ACTH and cortisol concentrations. Fig. 2 shows changes in maternal plasma ACTH concentration after intravenous vehicle or cocaine administration to the ewe. Maternal plasma ACTH concentration at +5 minutes after the 2.0 mg · kg^{-1} dose was greater than baseline and +60-minute values. By +60 minutes maternal ACTH was back to baseline levels.

Maternal plasma cortisol concentrations after vehicle or cocaine administration to the ewe are shown in Fig. 2. At the 0.5 mg · kg^{-1} dose maternal cortisol was only significantly elevated at +15 minutes (12.0 ± 2.89 ng · ml^{-1} versus 7.9 ± 0.82 mg · ml^{-1} at baseline, $p < 0.05$). Maternal cortisol level was significantly elevated at +5 and +15 minutes after the two highest doses (Fig. 2).

Effect of cocaine on fetal plasma ACTH and cortisol concentrations. The fetal ACTH response to maternal injection of cocaine was variable (Fig. 3). At 2.0 mg · kg^{-1} the increase in fetal ACTH was significant only at +5 minutes. After vehicle alone there was an initial drop in fetal plasma cortisol at +5 minutes ($p < 0.05$). No other values differed significantly from baseline after vehicle injection. The only other significant change was an increase in fetal plasma cortisol at +15 minutes after the 2.0 mg · kg^{-1} dose (Fig. 3).

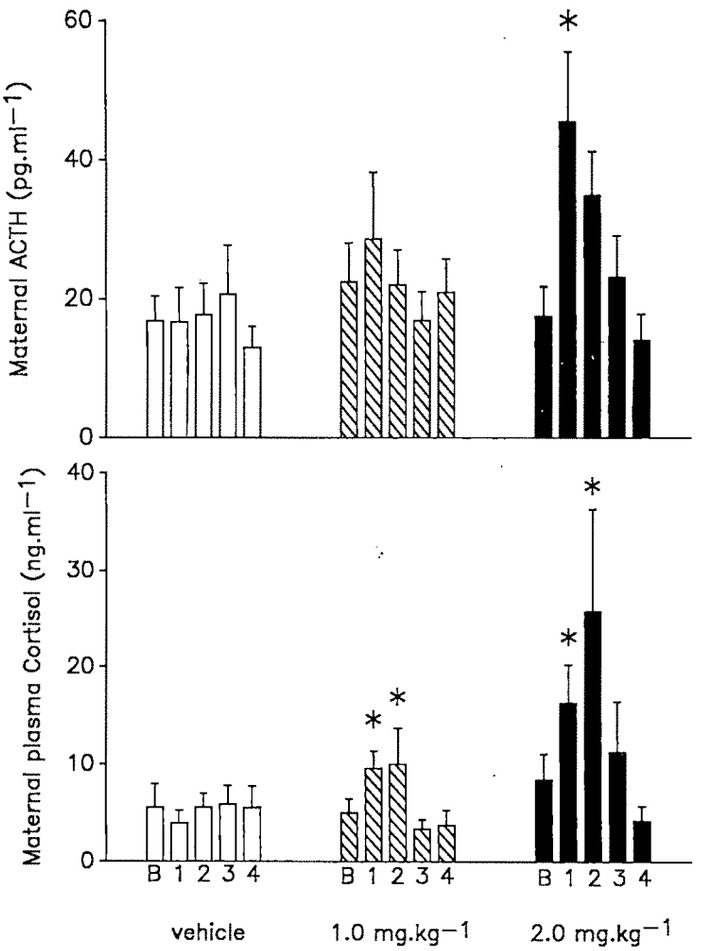

Fig. 2. Mean ± SEM ($n = 6$) maternal plasma ACTH and cortisol after injection of vehicle (□) or cocaine 1.0 mg · kg^{-1} (▨) or 2.0 mg · kg^{-1} (■) (*asterisk*, $p < 0.05$). *B* Represents the average of the samples at −30 and −20 minutes. *1*, *2*, *3*, and *4* Represent samples at +5, +15, +30, and +60 minutes, respectively.

Comment

We used the same doses of cocaine as Woods et al.[6] used in their study of the effect of cocaine on uterine blood flow in sheep in late pregnancy. At these doses the ewe showed some behavioral responses, including involuntary movements. The ewe often defecated at the lowest dose. On the basis of plasma concentrations of cocaine achieved in pregnant sheep after intravenous injection, the dose range of 0.3 to 1.0 mg · kg^{-1} corresponds to that customarily taken by addicted humans.[4] The maternal plasma levels obtained after injection of these doses were similar to the peak levels seen in human volunteers.[16]

As also reported by Woods et al.[6], we did not find any significant changes in maternal blood gas values after administration of vehicle or cocaine. However, there was a mild, transient fetal hypoxemia without alteration in fetal pH or P_{CO_2}. At the 2.0 mg · kg^{-1} dose the reduction in fetal P_{O_2} was significant at +5 minutes. The reduction in fetal oxygenation is most likely a result of decreased placental perfusion. Changes in fetal arterial P_{O_2} during decreased uterine blood flow are directly related to the degree of reduction in uteroplacental blood flow.[17] In the study of Woods et al.[6], a 2.0 mg · kg^{-1} dose of cocaine reduced uterine blood flow by 47%, because of a 168% increase in uterine vascular resistance with a fall in fetal P_{O_2} of about 5 mm Hg, returning to baseline in 15 minutes. We observed similar changes in P_{O_2}.

Administration of 2.0 mg · kg^{-1} cocaine led to a rapid increase in maternal plasma ACTH with a return to baseline by +60 minutes. The increase in maternal ACTH may be due to a direct action of cocaine on the maternal anterior pituitary[18] but is probably via a corticotropin releasing factor–dependent mechanism.[9] Maternal administration of cocaine in sheep is associ-

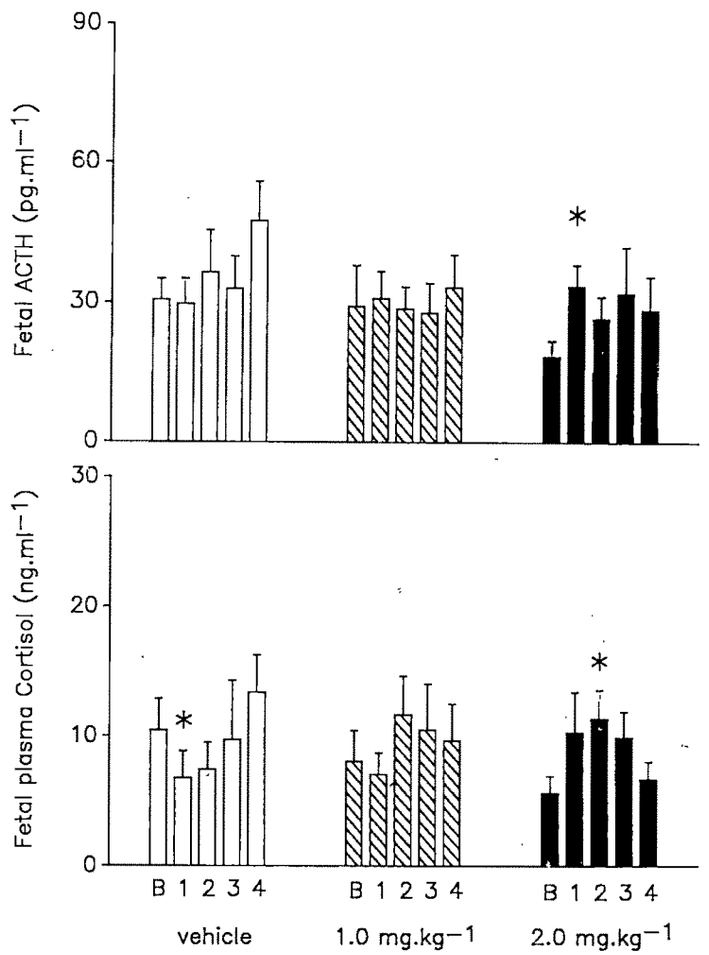

Fig. 3. Mean ± SEM ($n = 6$) fetal plasma ACTH and cortisol after injection of vehicle (□) or cocaine 1.0 mg · kg^{-1} (▨) or 2.0 mg · kg^{-1} (■) (*asterisk*, $p < 0.05$). *B* Represents average of samples at −30 and −20 minutes. *1, 2, 3,* and *4* Represent samples at +5, +15, +30, and +60 minutes, respectively.

ated with an increase in circulating catecholamines in both the ewe and the fetus.[4] The role of catecholamines in the regulation of ACTH secretion by sheep is unclear. Evidence exists for both stimulatory[19] and inhibitory[10] effects. In addition the release of catecholamines by cocaine may stimulate arginine vasopressin release.[8]

Maternal cortisol increased at all dose levels of cocaine. ACTH is normally released in a pulsatile fashion. The rise in maternal cortisol level is most likely explained by small undetected increases in maternal ACTH. The increase in maternal cortisol at the lowest dose of cocaine administered suggests that the maternal adrenal is probably sensitive to smaller rises in ACTH than can be detected significantly at our sampling frequency. Also cocaine may have a direct effect at the adrenal level on cortisol secretion.

The fetal ACTH response to maternal injection of cocaine was variable. In the 2.0 mg · kg^{-1} group there was a 95% increase in plasma ACTH concentration ($p < 0.05$) at +5 minutes. The large variability in the response may be related to the gestational age of the fetuses, as they were at a critical stage in the maturation of the hypothalamic-pituitary-adrenal axis. However, this increase in fetal plasma ACTH concentration is slightly larger than reported after comparable reductions in fetal oxygenation with oxytocin-induced uterine contracture.[20] The threshold for hypoxemia-induced fetal ACTH secretion is a 5 to 8 mm Hg reduction in carotid artery oxygen tension.[7] The level of fetal hypoxemia attained in our study (−3.2 ± 1.72 mm Hg) may not always have exceeded this threshold.

Cocaine may have a direct effect on fetal ACTH secretion. Although we did not measure plasma cocaine concentrations in either the mother or the fetus, it has been demonstrated that cocaine crosses the placenta rapidly after maternal injection[3, 4] and could possibly affect fetal ACTH secretion, especially at the highest

dose. Changes in fetal cortisol probably reflected the increase in fetal ACTH. The large variability seen in the response at the 0.5 mg · kg^{-1} dose suggests that this could have been around threshold for induction of cortisol release. It is also possible that an α-adrenergic discharge may have blunted some of the hypothalamic-pituitary-adrenal axis response to hypoxemia.[10]

In conclusion, we have demonstrated that intravenous administration of cocaine to ewes in late pregnancy is followed by an increase in maternal plasma ACTH and cortisol. The fetus responded with smaller increases in ACTH and cortisol. We speculate that these effects of cocaine during pregnancy represent changes in uterine blood flow leading to fetal hypoxemia together with direct stimulation of the hypothalamic-pituitary-adrenal axis. Further studies are needed to determine whether cocaine's effects are gestational age–dependent, especially later in pregnancy when the fetal adrenal gland is more sensitive to ACTH. In addition, information is required on the effects of long-term administration of cocaine on the maternal and fetal endocrine systems in pregnancy.

We thank Juliann Martel, statistician, and Susan Jenkins for help with the data analysis, and Xiu Ying Ding, Luce Guanzini, and Shawnee Riplog for their expert assistance with the experiments. We are grateful to Karen Moore for her assistance with the manuscript.

Human amniotic fluid modulation of collagenase production in cultured fibroblasts

A model of fetal membrane rupture

Felipe Vadillo-Ortega, MD, PhD,[a] Georgina González-Avila, MD, MSc,[b] Carlos Villaneuva-Diaz, MD,[a] José Luis Bañales, BSc,[b] Moisés Selman-Lama, MD, MSc,[b] and Alberto Alvarado Durán, MD[a]

Mexico City, Mexico

The participation of a mechanical factor as the only cause of rupture of fetal membranes during normal labor or premature rupture has been criticized, and the involvement of an enzymatic mechanism has been proposed. In this study we analyzed the effect of human amniotic fluids at different gestational ages on the collagenase synthesis of cultured fibroblasts. Our results show that term amniotic fluids are capable of inducing the synthesis of collagenase and other proteases in fibroblasts, as revealed by selective increases in collagenase activity and in immunoreactive collagenase. Nonterm amniotic fluids failed to do the same. This phenomenon is proposed as a model for studying the collagen degradation of fetal membranes during term gestation. (Am J Obstet Gynecol 1991;164:664-8.)

Key words: Collagenase, amniotic fluid, fibroblasts, premature rupture of membranes

Fetal membranes rupture is an event usually associated with delivery. In normal circumstances these structures remain intact until advanced cervical dilatation,[1] but in some women the rupture is not associated with labor and even occurs in the absence of contractions. Under these conditions there may be mother-newborn complications because prematurity and infections are strongly related to premature rupture of membranes (PROM).[2, 3]

A mechanical factor such as the unique determinant of normal or abnormal rupture has been criticized[4, 5] and it has been suggested that an enzymatic mechanism may be involved. This resembles cervical ripening in which the active degradation of extracellular matrix components, mainly collagen, plays a well-documented role and is a prerequisite for cervical dilatation.[6-8]

Two recent articles[9, 10] reported the existence of local collagenolytic activity in fetal membranes. We showed in samples from PROM that there are extensive changes in collagen metabolism, including an increase in collagenolytic activity.[10] The existence of collagenolytic activity in fetal membranes allows us to postulate its possible participation in chorioamnion ripening. The activity of this system must be switched on around the moment of labor, and its action must produce a diminution of the tensile strength of amnion mediated by a decrease in the collagen content.

This article presents evidence that indicates there are factor(s) that appear in term normal amniotic fluid that modulates collagenase synthesis in cultured fibroblasts.

Material and methods

Amniotic fluid sampling. Seventy-two amniotic fluid samples were collected from 12 to 40 weeks' gestation. Gestational age was determined by the patient's history. The nonterm samples were obtained from pregnant women undergoing diagnostic amniocentesis for antenatal diagnosis of congenital abnormalities. All samples used were from women whose babies had no genetic alterations. Term gestation amniotic fluid samples (38 to 40 weeks) were obtained at the moment of delivery. Grossly bloody samples were discarded.

Amniotic fluids were centrifuged at 10,000 *g* for 30 minutes in cold, sterilized by filtration through a 0.22 μm membrane (Millipore, Bedford, Mass.) and stored at −70° C until used. Prior to use, protein determination was performed with Bradford's method.[11] Unless otherwise indicated all reagents used were purchased from Sigma Chemical Co., St. Louis.

Fibroblast culture. Normal human fibroblasts (MRC-5 strain), obtained from the American Type Culture Collection, were seeded in 96 well plates and in 25 cm^2 tissue culture flasks (Flow, McLean, Va.). Cells were

grown to confluency in Earle's modified Eagle medium (Biofluids, Rockville, Md.) with 10% fetal calf serum added, 100 U/ml penicillin, 100 μg/ml streptomycin, and 250 ng/ml amphotericin B in 5% carbon dioxide and 95% air and a humid atmosphere for 5 to 7 days.

Before the experiments for collagenolytic activity or collagenase measurement were conducted, fetal calf serum was eliminated by replacing the culture media three times in 12 hours with fresh medium without fetal calf serum. During the last change, amniotic fluid was added at 15% to 20%, adjusting the volume by adding 300 μg of protein per milliliter of medium. Incubation was continued 24 hours under the same conditions. Each amniotic fluid sample was evaluated in quadruplicate. Four wells without addition of amniotic fluid were used as controls in each plate. As a positive control for stimulation of collagenase synthesis by fibroblasts, phorbol myristic acetate was used at a final concentration of 10 ng/ml.[12] The incubation was stopped by adding Triton X-100 at a final concentration of 0.1% and was maintained at 4° C for 2 hours. All supernatants were removed and each well or flask was individually assayed for enzymatic activity or enzyme measurement.

Collagenolytic activity. Enzyme activity was measured as described by Terato et al.[13] Type I collagen was extracted from human placenta with the pepsin-digestion method of Miller.[14] Radiolabeling of collagen was performed with a slight modification of Lefevere's method[15] with 5.0 mCi of acetic anhydride labeled with tritium (New England Nuclear, Boston, Mass.) instead of 25 mCi.

Labeled type I collagen (25 μg) with a specific activity of 800,000 disintegration per minute per milligram were incubated in duplicate for 24 hours with 25 μl of supernatant in each well. A buffer of Tris hydrochloride 50 mmol/L, pH 7.4, was added to achieve a final concentration of 0.15 mol/L sodium chloride 10 mmol/L calcium chloride, and 0.02% sodium azide. Collagen degradation was stopped by adding ethylenediaminetetraacetic acid at a final concentration of 80 mmol/L; 50% dioxane was added cold and samples were centrifuged at 10,000 *g* for 10 minutes. Supernatants were counted in a liquid scintillation spectrophotometer (Beckman LS-100, 59% efficiency). Control tubes were identical preparations with EDTA added at time zero. Collagenolytic activity was limited to EDTA-inhibitable tritium-labeled collagen degradation, and it was expressed as micrograms of degraded collagen per well per 24 hours.

The presence of latent collagenolytic activity was analyzed in 25 μl of supernatant preincubated for 30 minutes at room temperature with 10 μg/ml of L-1-Tosylamide-2-phenylethyl chloromethyl ketone-treated trypsin, then soybean trypsin inhibitor was added in tenfold excess (moles per liter). The optimum trypsin concentration for activation was documented previously with a range from 0.01 to 100 μg/ml at eight different points, as suggested by Bauer.[16] Another 25 μl aliquot was incubated in the presence of 1.0 mmol/L aminophenylmercuric acetate, a well-known collagenase activator.[17] These activated supernatants were incubated for collagenolytic activity as mentioned above.

Collagenolytic activity in each liquid used was assayed with the above methods.

A collagenase inhibitor has been isolated and well-characterized from amniotic fluid samples.[18, 19] To control the individual amniotic fluid inhibitory capacity on collagenolytic activity of media from stimulated fibroblasts, 7.5μg of amniotic fluid protein was incubated with 25 μl of unstimulated fibroblast medium that was previously activated with trypsin-limited proteolysis, and assayed for collagenase activity as described. This amount of amniotic fluid protein was equivalent to that used in the conditioning experiments. Inhibition was calculated and used for correction of collagenolytic activity in amniotic fluid–stimulated fibroblasts media.

Nonspecific protease activity. Heat-denatured tritium-labeled collagen was used as substrate for nonspecific protease activity with the method of Sunada.[20] Supernatant from each well 25 μl was incubated with 25 μg of substrate (20,000 counts per minute) at 37° C for 24 hours. Activity was expressed as micrograms of substrate degraded per 24 hours per well. Each amniotic fluid was also incubated alone, as a control, under these conditions.

Collagenase measurement. Media of amniotic fluid-conditioned and Triton X-100–treated fibroblasts cultured in flasks were collected and concentrated 10 times by ultrafiltration. Immunoreactive collagenase protein was quantified with the indirect inhibition enzyme-linked immunosorbent assay described by Cooper et al.[21] The enzyme for development of the standard curve and the specific antiserum were provided by Dr. Eugene Bauer from Stanford University.

Statistics. Statistical differences were assessed with the Mann-Whitney U test.

Results

Fibroblasts under basal conditions produced only latent collagenase, which could be fully activated with 10μg trypsin/ml. Activatable collagenolytic activity was 2.38 ± 1.32 μg of degraded collagen per well per 24 hours (n = 14). This basal activity was substracted from the results of all experimental wells. The immunoreactive collagenase in this media was 89.03 ± 9.79 ng/ml (n = 6). Fibroblast release of collagenase was 348.64 ± 36.32 ng/ml (n = 4) in response to stimulation by phorbyl myristic acetate.

Nonstimulated fibroblasts also released enzymes that degraded tritium-labeled gelatin. The values for this

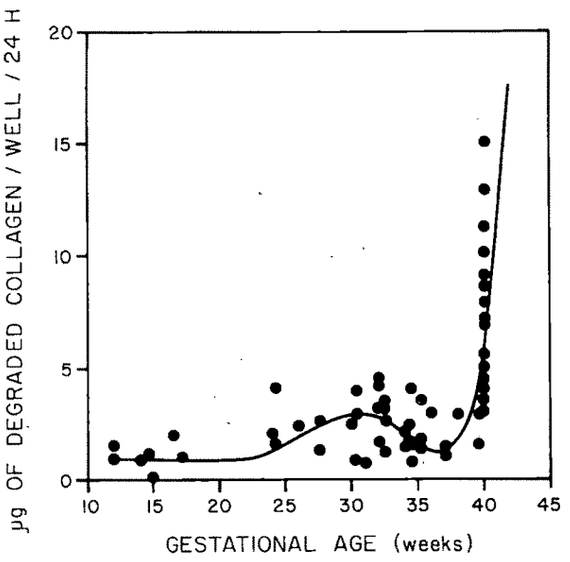

Fig. 1. Amniotic fluids from 12 to 40 weeks' gestation were added to fibroblasts in culture and incubated for 24 hours. Later, collagenolytic activity was assayed in the media. A clear stimulation of collagenase activity was observed when terminal amniotic fluids were used. All terminal amniotic fluids (38 to 40 weeks' gestation) are represented at point 40 on X axis.

enzymatic activity averaged 1.05 ± 2.32 µg of degraded gelatin per well per 24 hours (n = 14), and these values were substracted from degradation values in their respective experimental wells.

Amniotic fluids did not show collagenolytic activity at any gestational age. However, amniotic fluid from women ≥37 weeks' pregnancy had a nonspecific proteolytic activity against gelatin labeled with tritium. These values were used to correct the activity in their corresponding conditioned media.

We found some inhibitory effect of amniotic fluid on collagenolytic activity; however, it was not >5% under the experimental conditions. These individual values of inhibition were used to correct the collagenolytic activity in media of amniotic fluid-stimulated fibroblasts.

The addition of amniotic fluid to fibroblasts modified their basal production of collagenase and nonspecific proteases. A clear stimulation of these enzyme activities was observed when amniotic fluids captured during delivery from term gestations (38 to 40 weeks) were used (Figs. 1 and 2). In contrast, the use of amniotic fluid from nonterm, nondelivering gestations produced no effect because the values of active collagenase in media were similar to those from nonstimulated fibroblasts. Despite the fact that collagenolytic activity increased around week 30 (Fig. 1), the capacity for collagen degradation was very similar in all the media stimulated with nonterm amniotic fluid. Collagenolytic activity in media from fibroblasts stimulated with term amniotic fluid was 6.56 ± 3.15 µg of degraded collagen per well per 24 hours (n = 25). This activity was significantly higher ($p < 0.001$) when compared with the nonterm amniotic fluid induction (2.04 ± 1.11 µg degraded collagen, n = 47). Collagenolytic activity was in the active form in the media from amniotic fluid–stimulated fibroblasts and no further activation was obtained with trypsin or aminophenylmercuric acetate.

Measurements of immunoreactive collagenase showed a pattern that was very similar to the results from collagenolytic activity assay (Fig. 3). The media from nonterm, nondelivering amniotic fluid–induced fibroblasts contained 51.91 ± 25.86 ng collagenase per milliliter (n = 12), a value lower than the basal synthesis of nonstimulated fibroblasts ($p < 0.01$) and was clearly different from term amniotic fluid–stimulation (156.52 ± 32.37 ng/ml) ($p < 0.001$).

The pattern of nonspecific protease activity induction was similar to the collagenolytic activity. Term amniotic fluid–induced 11.35 ± 6.61 µg degraded tritium-labeled gelatin per well per 24 hours, whereas nonterm amniotic fluid only induced 0.67 ± 1.24 µg degraded tritium-labeled gelatin per well per 24 hours. These two groups were clearly different ($p < 0.0001$).

Comment

Degradation of extracellular matrix components requires a complex series of enzymatic activities. It is postulated that at the least three groups of proteases are involved in extracellular matrix catabolism. A group of enzymes degrades collagen-associated molecules such as proteoglycans and fibronectin and forms monomeric collagen. A second group directly attacks collagen and the third group hydrolyzes the collagen-degradation product until free aminoacids are obtained. Members of the first group are stromelysin and telopeptidase. The second group is formed by collagenases, a group of metalloenzymes with affinity for collagen that under physiologic conditions are a unique class of proteases capable of degrading native collagen. They are secreted in a latent form, and later, in the extracellular space, they are subjected to strict control. Its activity is dependent on complex interactions between the enzyme and inhibitors and activators. The last group of enzymes comprises several enzymes, such as gelatinase and PZ-peptide.[22, 23]

The results of this study reveal that amniotic fluids from term pregnancies contain chemical signals that enhance the in vitro synthesis of collagenase and other proteases in cultured fibroblasts. The fact that such effect had a clear association with the end of gestation suggests that it may play a role in vivo in the degradation of the extracellular matrix of fetal membranes during normal labor. Because preformed collagenase

is not stored inside fibroblasts,[24] the effect of amniotic fluid was possible because of an induction of collagenase synthesis, which is in agreement with the finding of increased enzymatic activity and immunoreactive protein quantity. On the other hand, the possibility of latent enzyme activation was controlled with the use of the collagenase activators aminophenylmercuric acetate and trypsin.

Amniotic fluids from nonterm gestations appear to inhibit the synthesis of collagenase as revealed by the immunoreactive measurement of this enzyme. However, its activity in media did not show this behavior, probably because nonlimiting conditions for enzyme activity were used.

The media from amniotic fluid-conditioned fibroblasts contained active collagenase only, as suggested by the fact that addition of the collagenase activators to the wells did not induce further collagenase activity. This could be explained by a collagenase activator already present in the system, which may be ascribed to the action of some of the induced nonspecific proteases. Characterization of these enzymes is mandatory to clarify this point.

The use of a fibroblast cell line as a model of the biochemical events that may occur in fetal membranes during labor is acceptable because this cellular population is a normal constituent of these tissues. We hypothesized that activation of local fibroblasts by a signal present in term amniotic fluid induces the synthesis of collagenase and other proteases. The subsequent degradation of collagen, which is the main structural component of membranes, diminishes the mechanical support of these tissues. At this moment the membranes are more fragile and a sudden increase in intrauterine pressure would lead to their rupture.

The identification of this mechanism opens the possibility of studying its participation in PROM because, as we have shown, in PROM there appears to be an increase in collagen degradation.[10]

It has been suggested that activation of local collagenolytic activity in amnion may be promoted by external factors such as inflammation and infection. In this context, it has been postulated that collagen degradation that occurs in PROM is caused by inflammatory cells, including polymorphonuclears and macrophages, through the synthesis of collagenase and other proteases.[4, 25] However, as suggested by this study, it is also possible that under normal or pathologic conditions, collagenolysis may be activated by local normally resident cells such as fibroblasts. It has been shown that fibroblasts respond to macrophage and lymphocyte signals with the synthesis of collagenase, stromelysin, and other connective tissue-degrading metalloproteases.[23, 26]

Characterization of the molecular nature of the compounds with activity on fibroblasts may be crucial in the search for the factors involved in normal, and probably abnormal, rupture of the membranes. A possible candidate for such a compound is prostaglandin E_2, be-

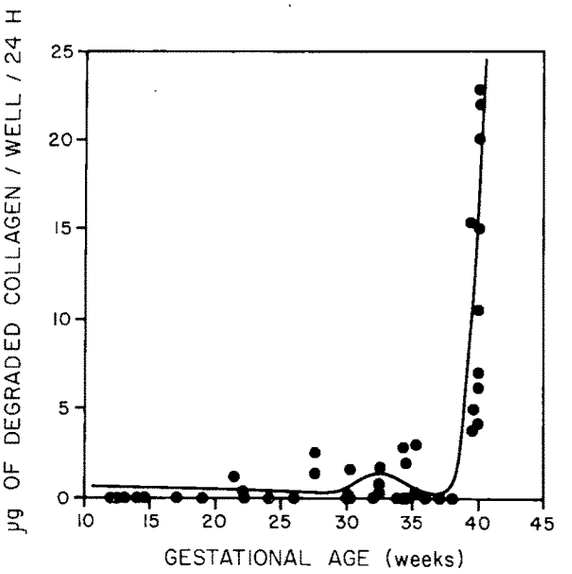

Fig. 2. Proteolytic activity against gelatin tagged with tritium was assayed in media of fibroblasts stimulated by amniotic fluid. Pattern of these proteases was similar to collagenolytic activity and showed peak of activity when terminal amniotic fluid was used. Terminal amniotic fluids (38 to 40) are grouped at point 40 on X axis.

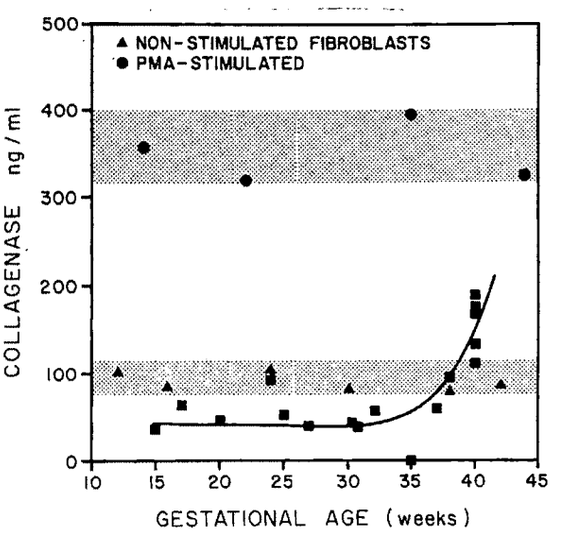

Fig. 3. Immunoreactive collagenase in media from fibroblasts stimulated by amniotic fluid was quantified with indirect inhibition enzyme-linked immunosorbent assay. Pattern of protein was similar to collagenolytic activity (■). As controls of fibroblast functionality, nonstimulated fibroblasts and phorbol myristic acetate–stimulated cells were included.

cause this molecule appears to be related to events in human labor under normal or abnormal circumstances, and it has been shown that this substance stimulates the production of collagenase.[27, 28]

The initiation of human labor is associated with mobilization of arachidonic acid from fetal membranes; and increased concentrations of prostaglandin E_2 in the amniotic fluid has been detected.[29] In addition, increased levels of this compound have been quantified in amniotic fluid of women with preterm labor,[30] and in the presence of infection, the latter mediated through endotoxins that stimulate amnion cells to synthesize prostaglandin E_2.[31] In this way it is possible to hypothesize that an unidentified signal in normal circumstances or bacterial products in pathologic conditions induce the synthesis of prostaglandins, especially prostaglandin E_2, and that this substance may then stimulate the synthesis of collagenase in local cell populations, which in turn allows PROM.

Epidermal growth factor receptor expression in normal ovarian epithelium and ovarian cancer

I. Correlation of receptor expression with prognostic factors in patients with ovarian cancer

Durham, North Carolina

Previous studies in breast and bladder cancer have suggested that epidermal growth factor receptor is expressed by only a proportion of cancers and is associated with poor clinical outcome. We used a monoclonal antibody specifically reactive with the extracellular domain of the epidermal growth factor receptor to localize this receptor immunohistochemically in frozen sections of normal ovary and epithelial ovarian cancer. Normal ovarian epithelium was found to express epidermal growth factor receptor in all cases. Among 87 ovarian cancers, however, 23% did not express immunohistochemically detectable receptor. Epidermal growth factor receptor expression was not related to histologic grade or stage, but was associated with poor survival ($p < 0.05$). The median length of survival of patients with tumors that did not express epidermal growth factor receptor was 40 months compared with 26 months in patients with tumors that did express epidermal growth factor receptor. As in breast and bladder cancer, expression of epidermal growth factor receptor in ovarian cancer appears to be a poor prognostic factor. (AM J OBSTET GYNECOL 1991;164:669-74.)

Key words: Epidermal growth factor receptor, epidermal growth factor, ovarian cancer

The epidermal growth factor receptor is a cell surface molecule that is widely distributed in normal human tissues. In vitro, after binding of one of its ligands, either epidermal growth factor or transforming growth factor-α, to the extracellular domain of the receptor, the tyrosine kinase of the intracytoplasmic domain is activated. This results in the generation of second messengers that transmit the mitogenic signal to the nucleus.[1] In vivo, the epidermal growth factor receptor and its ligands are thought to play a role in normal growth and differentiation although the precise nature of this involvement is not understood.

Abnormal expression of the epidermal growth factor receptor and its ligands has been associated with malignant transformation. Initially, it was noted that viral transformation of normal rat fibroblasts is associated with expression of transforming growth factor-α, which acts to stimulate growth by binding to epidermal growth factor receptors that are present on the same cells.[2] This phenomenon has been referred to as autocrine growth stimulation. Abnormal expression of epidermal growth factor receptor and its ligands also has been noted in human cancers. In breast cancer it has been shown that only one third of cases express detectable epidermal growth factor receptor, and that epidermal growth factor receptor expression is inversely related to estrogen receptor expression and associated with poor prognosis.[3, 4] Conversely, squamous cell cancers frequently overexpress epidermal growth factor receptor, although a direct relationship between overexpression and biologic behavior has not been demonstrated convincingly.[5, 6] Previously, we examined the relationship between epidermal growth factor receptor expression and prognostic factors in endometrial cancer.[7] We found that most, but not all, endometrial cancers express epidermal growth factor receptor, but no relationship to steroid receptor status or prognosis was noted.

Although epithelial ovarian cancer causes more deaths than all other gynecologic cancers combined,

few studies have been performed to examine the relationship between epidermal growth factor receptor expression and the biologic behavior of ovarian cancer. In the present study, we used a monoclonal antibody reactive with the extracellular domain of the epidermal growth factor receptor to examine expression of this receptor in frozen sections of normal ovary and epithelial ovarian cancer. Epidermal growth factor receptor expression in the cancers was contrasted to that of normal epithelium, and the relationship between receptor expression and prognostic factors and survival in ovarian cancer was examined.

Material and methods

Patients. All the patients in this study with ovarian cancer underwent exploratory laparotomy in conjunction with treatment for epithelial ovarian cancer at Duke University between 1985 and 1989. Frozen tumor samples from 87 patients were found to be adequate for immunohistochemical analysis. Tumor was obtained at the initial operation in 57 cases (7 stage I or II, 50 stage III or IV). Among these 57 patients, five also had tumor samples frozen at second-look or subsequent laparotomy. In an additional 30 patients, tumor samples were obtained only at second-look laparotomy or at the time of recurrence (7 stage I or II, 23 stage III or IV). In addition, samples of normal ovary were frozen from six patients undergoing hysterectomy and bilateral salpingo-oophorectomy for benign gynecologic diseases.

All histologic material from the 57 patients in whom tumor samples were obtained at initial surgery was reviewed by a single pathologist (A.K.) and the histologic type (serous, mucinous, clear cell, endometrioid, undifferentiated) and histologic grade (well differentiated, moderately differentiated, poorly differentiated) were determined with the use of the World Health Organization criteria.[8] Most of the other 30 patients from whom tumor samples were obtained at a subsequent operation had undergone initial surgery elsewhere and slides were not available for review. However, in these 30 patients the diagnosis of epithelial ovarian cancer was confirmed by review of material obtained at a subsequent surgical procedure.

Immunohistochemistry. All tissue samples were snap-frozen and stored at −70° C until analyzed. Tissue samples were frozen in tissue Tek O.C.T. compound (Ames Division, Miles Laboratories, Elkhart, Ind.) and 4 to 6 μm thick cryosections were mounted on gelatin-coated slides. The slides were air dried overnight at room temperature to enhance the cellular morphology. The slides were fixed in acetone for 10 minutes at room temperature and then air dried again for 30 minutes. Then the slides were washed in phosphate-buffered saline solution three times for 5 minutes.

Immunohistochemical staining was performed with the Elite Vectastain ABC kit (Vector Laboratories, Burlingame, Calif.). Slides were placed in a humidified chamber and incubated for 15 minutes with several drops of a 1:200 dilution of horse serum in phosphate-buffered saline solution with 2% bovine serum albumin. Then, 70 μl of primary antibody was applied over the tissue sections for 60 minutes. After washing with phosphate-buffered saline solution, biotinylated goat antimouse immunoglobulin G (IgG) antibody was added for 30 minutes followed by the avidin-peroxidase complex. Finally, the slides were developed for 4 minutes with the enzyme substrate diaminobenzidine (0.5% diaminobenzidine in 0.05% Tris hydrochloride buffer, 0.6% hydrogen peroxide). The slides then were rinsed for 10 minutes in running tap water, counterstained with 1% methyl green (Sigma Chemical Co., St. Louis), dehydrated, and mounted.

Monoclonal antibodies. Purified 528 is a murine monoclonal antibody that is specifically reactive with the extracellular domain of the epidermal growth factor receptor. This antibody was generated by immunization of mice with A431 cells, which expressed markedly increased numbers of epidermal growth factor receptors[9] (528 was the generous gift of John Mendelsohn, Memorial Sloan-Kettering Cancer Center, New York). We tested 528 at concentrations of 0.01 to 5.0 μg/ml and determined that maximal immunohistochemical staining of the epidermal growth factor receptor was obtained with a concentration of 1.0 μg/ml. This concentration of antibody subsequently was used to stain all the tissue samples in this study. We used purified mouse IgG specific for nonhuman tissue (Coulter Immunology, Hialeah, Fla.) at a dilution of 1:100 as a negative control. Anticytokeratin AE1/AE3 antibodies (Boehringer-Mannheim Biochemicals, Indianapolis) were used as a positive control.

Immunohistochemical staining of the epidermal growth factor receptor was evaluated with serial sections. First, a section stained with hematoxylin and eosin was examined to evaluate the histology. Then a negative control slide stained with nonspecific mouse IgG was examined to assess nonspecific staining. A positive control slide stained with anticytokeratin antibodies was examined to confirm the presence of viable tumor cells in the section. Cases in which the negative or positive controls were not adequate were repeated. Finally, the slide in which 528 was used as the primary antibody was examined. The intensity of staining for epidermal growth factor receptor was graded as 0 (staining not greater than negative control), 1+ (light staining), 2+ (moderate staining), or 3+ (heavy staining). The intensity of staining recorded was the consensus of two observers who used a double-headed microscope. The identity of the patients was not known to the observers while the slides were being scored.

Statistics. Tables were analyzed with Fisher's two-

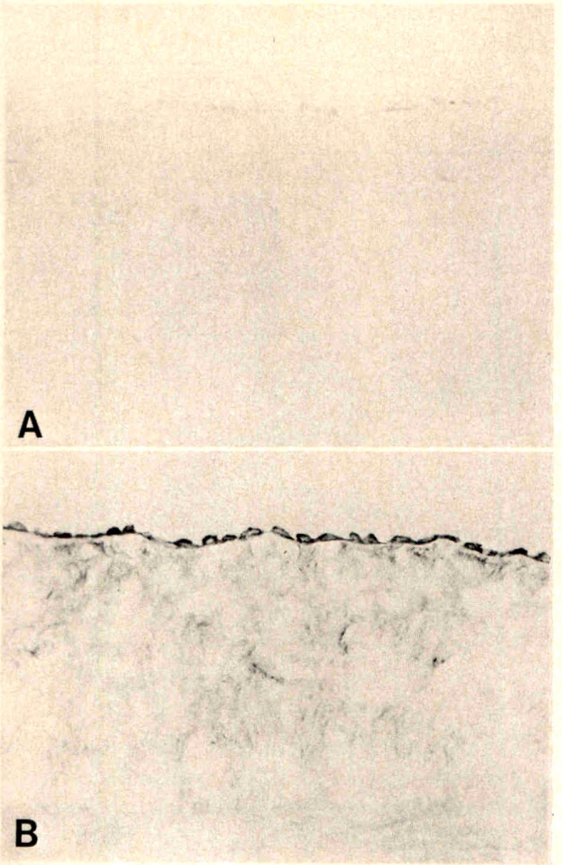

Fig. 1. Immunohistochemical staining of epidermal growth factor receptor in normal ovarian epithelium, **A,** negative control; **B,** epidermal growth factor receptor.

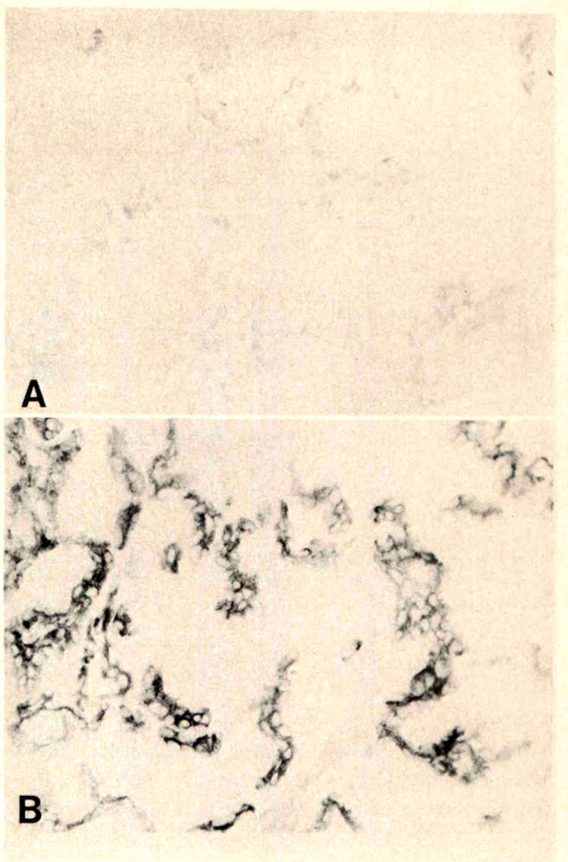

Fig. 2. Immunohistochemical staining of epidermal growth factor receptor in ovarian cancer, **A,** negative control; **B,** epidermal growth factor receptor.

tailed exact test. Survival estimates were calculated with the Kaplan-Meier life table method.[10] Differences in survival were tested with the log rank statistic.[11]

Results

Immunohistochemically detectable epidermal growth factor receptor was seen in normal ovarian epithelium in all cases examined. Homogeneous staining of all epithelial cells was noted in each case. In three cases, light staining was noted, and in three cases moderate staining was seen (Fig. 1, *A* and *B*). In all cases, lighter staining of the underlying stroma also was observed.

Among the 57 patients with ovarian cancer in whom tumor was frozen at initial surgery, 41 patients had serous tumors, 6 patients had mucinous tumors, 3 patients had endometrioid tumors, 2 patients had clear cell tumors, 4 patients had undifferentiated tumors, and 1 patient had a mixed serous-clear cell tumor. Among these 57 patients, cancer was well-differentiated in 6, moderately differentiated in 23, and poorly differentiated in 28. Staining for epidermal growth factor receptor was absent in 11 (19%), light in 18 (32%), moderate in 22 (38%), and heavy in 6 patients (11%). In addition to staining in the malignant epithelial tissue component, staining frequently was seen in the accompanying stroma (Fig. 2, *A* and *B*). In 11 patients with advanced-stage disease, tumor samples were obtained from multiple sites at the time of initial cytoreductive surgery. In these patients, epidermal growth factor receptor expression was evaluated in both the primary tumor and in one to three metastases. In all cases, the intensity of staining for epidermal growth factor receptor within a single patient was similar in the primary tumor and metastases. In addition, in five patients epidermal growth factor receptor expression was evaluated in tumor samples obtained both at initial surgery and at a subsequent laparotomy. In all cases, the intensity of staining for epidermal growth factor receptor was unchanged after therapy.

Because epidermal growth factor receptor expression did not appear to be altered during the course of treatment, we also analyzed epidermal growth factor receptor expression in an additional 30 tumor samples

Table I. Relationship between epidermal growth factor receptor expression and prognostic factors in advanced epithelial ovarian cancer

obtained from patients at the time of second-look or other subsequent laparotomy. Among these 30 patients, staining for epidermal growth factor receptor was absent in 9 (30%), light in 8 (27%), moderate in 13 (43%), and heavy in none (0%).

Overall, among all the patients in this study, epidermal growth factor receptor was absent in 20 of 87 cases of ovarian cancers studied (23%). Epidermal growth factor receptor was absent in 5 of 14 patients who had stage I or II disease (36%) compared with 15 of 73 patients who had stage III or IV disease (21%). In Table I, the relationship between epidermal growth factor receptor expression and other prognostic factors is presented for the 50 patients with stage III or IV disease in whom tumor samples were obtained at primary surgery. There was no significant relationship between epidermal growth factor receptor expression and histologic grade or the ability to perform an optimal cytoreductive operation that left no tumor nodule >1 cm in diameter.

Table II examines the relationship between epidermal growth factor receptor expression and response to primary therapy in the 73 patients with advanced-stage disease. Among the 15 patients whose tumors did not express epidermal growth factor receptor, 4 patients (27%) did not undergo second-look laparotomy because of patient refusal or poor medical condition. Among the 58 patients with tumors in which staining for epidermal growth factor receptor was seen, 13 (22%) did not undergo second-look laparotomy. Although 5 of 15 patients whose tumors did not express epidermal growth factor receptor achieved a negative second-look laparotomy (33%) compared with only 8 of 49 evaluable patients whose tumors did express epidermal growth factor receptor (16%), this difference was not statistically significant ($p = 0.1$).

In Fig. 3, the relationship between epidermal growth factor receptor expression and survival is shown. Among all 87 patients, survival of patients whose tumors did not express epidermal growth factor receptor was significantly better than that of patients whose tumors did express epidermal growth factor receptor ($p < 0.05$). The median survival of patients whose tumors did not express epidermal growth factor receptor was 40 months compared with 26 months in patients whose tumors did express epidermal growth factor receptor. If only the 73 patients with stage III or IV disease are considered, the survival advantage for epidermal growth factor receptor–negative cases was at the limit of statistical significance ($p = 0.06$). The median survival of patients whose tumors did not express epidermal growth factor receptor was 37 months compared with 21 months in patients whose tumors did express epidermal growth factor receptor.

Comment

Previously, it was shown that epidermal growth factor receptor is expressed by a wide range of normal human cells of both epithelial and mesenchymal origin. For example, in the uterus, we and others have shown that epidermal growth factor receptor is expressed by endometrial glands, endometrial stromal cells, and myo-

metrium.[7, 12] Similarly, in this study both the surface epithelium and underlying stroma of the ovary were found to express epidermal growth factor receptor. The physiologic role of epidermal growth factor receptor in the ovary remains unknown.

Studies of epidermal growth factor receptor expression in human cancers generally have found that epidermal growth factor receptor levels are increased in some squamous cell cancers, whereas a proportion of adenocarcinomas appear to have lost epidermal growth factor receptor relative to normal glandular epithelium. In some but not all studies, alterations in epidermal growth factor receptor expression were found to correlate with clinical outcome. For example, a group from Newcastle, England, found that absence of epidermal growth factor receptor is associated with favorable clinical outcome in patients with breast[3, 4] and bladder cancer.[13] Conversely, in lung[14] and endometrial[7] adenocarcinomas, no such relationship was noted. In squamous cell cancers of the lung, one group reported that those with the highest levels of epidermal growth factor receptor (greater than fivefold increased) have poor survival rates.[15] However, other studies of squamous cell cancers arising in the head and neck[6] and other sites have not confirmed these findings.

Although ovarian cancer causes more deaths than all other gynecologic cancers combined, little data have been reported with regard to epidermal growth factor receptor expression in ovarian cancer. A single study reported that high epidermal growth factor receptor expression in ovarian tumors correlated with a favorable prognosis.[16] However, in this study all adnexal tumors including epithelial, germ cell, and stromal tumors were analyzed together. In the present study, we examined epidermal growth factor receptor expression in a group of patients with epithelial ovarian cancer with the use of an immunohistochemical technique. Immunohistochemically detectable epidermal growth factor receptor was not seen in 23% of cases. This incidence of epidermal growth factor receptor negativity is similar to that found in other immunohistochemical studies of epidermal growth factor receptor in lung[14] and endometrial cancers.[7] On the other hand, studies that assess epidermal growth factor receptor expression by measuring binding of radiolabeled epidermal growth factor to tissue homogenates usually report a higher incidence of epidermal growth factor receptor negativity, for example, one half to two thirds in breast cancer.[3, 4] Some of the differences in conclusions between different studies of the same type of cancer may relate to these methodologic differences. Whereas binding assays are quantitative, it is clear that benign stromal elements in homogenized tumor samples contribute to epidermal growth factor receptor content. On the other hand, although immunohistochemical techniques allow direct assessment of epidermal growth factor receptor expression by cancer cells, evaluation of the intensity of staining is subjective.

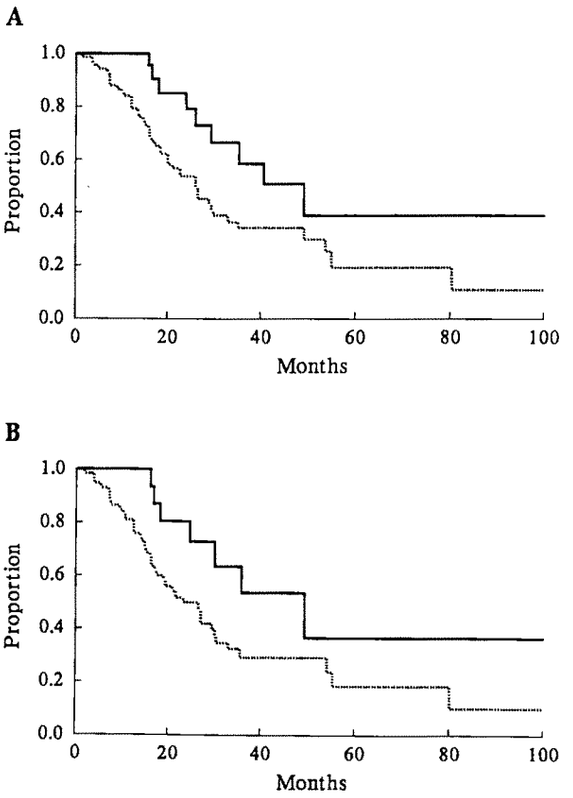

Fig. 3. Relationship between epidermal growth factor receptor expression and survival of patients with ovarian cancer (*solid line*, epidermal growth factor receptor negative; *dashed line*, epidermal growth factor receptor positive), **A**, all 87 patients ($p < 0.05$); **B**, 73 patients with advanced-stage disease ($p = 0.06$).

In this initial study, with the use of univariate analysis, we found a statistically significant relationship between epidermal growth factor receptor expression and survival in patients with epithelial ovarian cancer. Similar to breast and bladder cancer, absence of detectable epidermal growth factor receptor was associated with better long-term survival. Furthermore, although not statistically significant because of the small number of early stage patients, we found that absence of epidermal growth factor receptor was more common in stage I or II tumors (36%) compared with stage III or IV tumors (21%). This also is suggestive that absence of epidermal growth factor receptor is associated with cancers of lower biologic aggressiveness. Larger studies in which multivariate analysis can be used are needed to determine whether epidermal growth factor receptor status is an independent prognostic factor in ovarian cancer.

More recently, two other membrane-spanning

receptor-like molecules were discovered that have a high degree of homology to the epidermal growth factor receptor. The first, HER-2/neu (c-*erb* B2),[17] has been reported by Slamon[18] to be overexpressed in approximately 30% of breast and ovarian cancers. We confirmed the association between HER-2/neu overexpression and poor prognosis in ovarian cancer.[19] Both Slamon's study and ours found that the prognostic value of HER-2/neu overexpression in ovarian cancer was much stronger than that observed for epidermal growth factor receptor status in the present study. In addition, more recently, a third member of the *erb* B family (c-*erb* B3) has been identified.[20] It has been noted that c-*erb* B3, like c-*erb* B2, is overexpressed in some breast cancers. No studies of c-*erb* B3 expression in ovarian cancer have been performed to date. In the future, in addition to studies such as the present one that examine the prognostic significance of receptor expression, it will be critical to determine the actual biomolecular role of the c-*erb* B family of receptors in the process of malignant transformation of normal ovarian epithelium.

We thank Regina Whitaker and Bennie Penny for their expert technical assistance.

Dose effects of antenatal corticosteroids for induction of lung maturation in preterm rabbits

Bannie L. Tabor, MD,[a] Evelyn D. Rider, MD,[b] Machiko Ikegami, MD, PhD,[b] Alan H. Jobe, MD, PhD,[b] and James F. Lewis, MD[b]

Torrance, California

Dose-response effects of corticosteroids were investigated in the preterm rabbit. Pregnant rabbits were given two doses of 0.01, 0.03, or 0.1 mg of betamethasone per kilogram every 24 hours, beginning on day 25 of gestation. Saline solution was used in a comparison treatment group. Half of the newborn rabbits received supplemental surfactant therapy after delivery via cesarean section on day 27, and all were ventilated on a ventilator-plethysmograph system for 30 minutes. The 0.01 and 0.03 mg/kg regimens had no effect on birth weight or lung function. The 0.1 mg/kg regimen resulted in fetal growth retardation and improved ventilatory measurements, gas exchange, and decreased protein accumulation in the lung, without increasing surfactant pool size. The induction of lung maturation by corticosteroids has multiple targets in the developing lung and does not exhibit a linear dose response. (AM J OBSTET GYNECOL 1991;164:675-81.)

Key words: Surfactant, pulmonary edema, compliance

Antenatal administration of corticosteroids has been used to induce pulmonary maturation and prevent respiratory distress in the preterm neonate.[1] Extensive laboratory and clinical studies have established the efficacy of corticosteroids, although the major effects of corticosteroids on the developing lung remain unclear. The preterm rabbit has served as a model for numerous investigations of lung maturation. Fetal growth retardation occurs in both rabbits and rodents with corticosteroid doses noted to alter lung development. The growth retardation is presumed to be due to effects on glycogen stores or decreased uteroplacental perfusion that is secondary to placental degeneration, resulting in decreased fetal oxygenation and substrate availability.[1] Most studies of lung maturation in preterm rabbits have used doses of betamethasone of 0.1 to 0.2 mg/kg maternal body weight, although a dose of 0.05 mg/kg was shown to have effects on lung maturation (increased dynamic compliance, improved pressure-volume relationships, and decreased protein leak into the lung) that were similar to those at higher doses.[2] The goal of this study was to identify the minimal effective corticosteroid dose that would influence lung maturation and to see if maturational responses could be dissociated from growth effects on the fetus.

Material and methods

Corticosteroid treatments. Time-bred New Zealand White rabbits were randomized to one of four treatment regimens beginning on day 25 of gestation (term = 31 days). The three hormonal treatment groups received maternal intramuscular injections of betamethasone (Celestone Soluspan; Schering Corp., Kenilworth, N.J.) at doses of 0.01, 0.03, and 0.1 mg/kg maternal body weight, respectively, every 24 hours for two doses. These doses were chosen because 0.1 mg/kg is known to be an effective dose, whereas 0.01 and 0.03 mg/kg were lower than the lowest dose of 0.05 mg/kg that has been shown to be effective.[2] A control group received 0.2 ml of saline solution on a similar dosing schedule. The guidelines for the care and use of animals approved by our institution were followed during the experiment.

Preparation of rabbits. On day 27 of gestation the pregnant does were given intravenous diazepam and supplemental oxygen via face mask and delivered via cesarean section with spinal anesthesia. The newborn rabbits were weighed and given 10 mg/kg ketamine and 0.1 mg/kg acepromazine by intraperitoneal injection. Alternate rabbits from each litter received 0.2 ml of 0.45% sodium chloride, containing either 1 μCi iodine 125–albumin or natural sheep surfactant (50 mg total lipid per kilogram) with 1 μCi ^{125}I-albumin. These suspensions were administered via a tracheal tube made from an 18-gauge needle, which was tied into the trachea.[3] Surfactant therapy was included in the protocol because synergistic action between surfactant treatment and antenatal corticosteroids has been noted in this model.

Five breaths of 100% oxygen were given with an anesthesia bag to initiate ventilation after the intratracheal injection. The rabbits were then transferred to a ventilator-plethysmograph system that was temperature controlled at 37° C.[3] Initially, ventilation was given with 100% oxygen at a rate of 40 breaths per minute, an inspiratory time of 0.7 second, a peak inspiratory pressure of 35 cm H_2O, and an end-expiratory pressure of 0. Tidal volume was measured frequently with a pneumotachometer and maintained at 10 to 12 ml/kg by adjusting the individual peak inspiratory pressures.[3]

Each rabbit received 0.2 ml of saline solution containing 1 μCi iodine 131–albumin via the external jugular vein immediately after placement on the ventilator. The rabbits were ventilated for 30 minutes and then sacrificed with intrathecal injections of lidocaine. The chest was opened and a heparinized blood sample was drawn from the heart. An aliquot of this sample was used to measure P_{CO_2}. A second aliquot was used for measurements of labeled albumin and hemoglobin concentration. The sex of each rabbit was determined by examination of the internal gonads.[4]

Processing of samples. The lungs of the newborn rabbits were thoroughly lavaged with five aliquots (1 to 1.5 ml each) of 0.9% sodium chloride.[3] The pooled volume was recorded as the alveolar wash. The lungs were removed and weighed. The alveolar wash, lungs, and blood aliquots, along with triplicate samples of the ^{131}I and ^{125}I used for the initial injections, were counted for radioactivity. The lungs were then homogenized in 4 ml of 0.9% saline solution and the volume was recorded. The contribution of intravascular blood to the radioactivity associated with the lung was calculated by measuring the hemoglobin content and radioactivity of the blood and the lung and subtracting from the total radioactivity of the lung.[3]

Lipid extracts of aliquots of the alveolar wash and the lung homogenate were prepared with chloroform/methanol (2:1, vol/vol).[5] The extracts were treated with osmium tetroxide, and saturated phosphatidylcholine was isolated by alumina column chromatography and quantified by phosphorus assay.[6, 7]

Material. Radiolabeled albumin was prepared by iodination with carrier-free ^{131}I or ^{125}I and with the use of chloramine-T and monomer standard bovine serum albumin (Miles Laboratories, Elkhart, Ind.). The iodinated albumin was extensively dialyzed, and the incorporation was verified by trichloroacetic acid precipitation. The surfactant was isolated by a series of differential and sucrose density-gradient centrifugation steps from alveolar washes from adult sheep.[8]

Data analysis. Animals were excluded from the final analysis if upper airway leaks occurred during placement of the trachea tube, a pneumothorax occurred during ventilation, or the final P_{CO_2} was >70 mm Hg. The ^{125}I-albumin and ^{131}I-albumin radioactivity of the alveolar wash and the lung tissue was expressed as the percent recovery of the respective quantities injected. A final compliance value was calculated for each rabbit 30 minutes after the initiation of ventilation by dividing the measured tidal volume (in milliliters) by the peak inspiratory pressure (in centimeters of water) and the body weight (in kilograms). A ventilatory efficiency index was calculated for each rabbit as a measure of ventilation and gas exchange that compensates for the effects of ventilatory pressures, rate, and P_{CO_2}.[9] Ventilatory efficiency index = $3800/P \times F \times Paco_2$), where 3800 is a constant relating to carbon dioxide production, P is the peak inspiratory pressure minus positive

‡$p < 0.05$, versus control.

end-expiratory pressure, F is ventilatory frequency, and P_{aCO_2} is arterial carbon dioxide pressure. All values are reported as means ± SEM. Statistical analysis was performed with one-way analysis of variance followed by the Student–Newman-Keuls correction for multiple comparisons. Two-way analysis of variance was used to identify any sex-dependent interactions with treatment groups. No sex differences in any parameters were noted, so sexes within groups were combined for subsequent analysis. Significance was accepted at $p < 0.05$.

Results

Condition of animals. The number of litters and fetuses, mean birth weights of all live-born rabbits, and the number of animals excluded from analysis are described in Table I. The mean antenatal loss rate was higher in the litters receiving the 0.1 mg/kg betamethasone dosing regimen, but was not significant ($p > 0.1$). In addition, the mean birth weight in this group was significantly less than in the others ($p < 0.01$). The mean birth weights in the low-dose steroid groups were virtually identical to those of the control group. There were no differences in the incidence of tracheal leaks and final P_{CO_2} values >70 mm Hg. The only difference between the groups in terms of exclusion criteria occurred in the non-surfactant-treated groups, where the control group had a higher incidence of pneumothoraces ($p < 0.05$).

Ventilatory status. The ventilator strategy was successful in maintaining mean tidal volumes in the desired range for all treatment groups (Table II). The mean P_{CO_2} values were similar between the hormonal treatment regimens, when considered within the respective surfactant treatment groups. In the absence of supplemental surfactant therapy, the lower-dose steroid groups had mean peak inspiratory pressures similar to those of the control group, whereas the 0.1 mg/kg group required significantly lower pressures ($p < 0.01$). The control animals that sustained pneumothoraces had a mean peak inspiratory pressure of 32.0 ± 1.2 mm Hg at the time of the pneumothorax, which was similar to that of all but the 0.1 mg/kg group ($p < 0.01$). In the surfactant-treated groups the 0.1 mg/kg group had a lower mean peak inspiratory pressure than the 0.01 mg/kg ($p < 0.05$) and the 0.03 mg/kg ($p < 0.01$) groups but was not significantly lower than that of the control group. However, the 0.03 mg/kg group did require higher pressures than the control group ($p < 0.05$). Similar results were found in compliance (Fig. 1). Among the non-surfactant-treated groups the rabbits in the 0.1 mg/kg group were more compliant than the others ($p < 0.05$). With the addition of surfactant treatment, the highest-dose steroid group had higher compliance values than the others but the difference was significant only in comparison with the 0.01 and 0.03 mg/kg steroid groups ($p < 0.05$). The 0.1 mg/kg group also had a higher ventilatory efficiency index than the other groups, both with and without surfactant treatment, but this was significant only among the non-surfactant-treated rabbits ($p < 0.05$) (Fig. 1).

Surfactant pool size. The amount of saturated phosphatidylcholine in the alveolar wash and the total lung (lung homogenate plus alveolar wash) was measured to assess the effects on surfactant pool size. In the non-surfactant-treated groups there were no differences in terms of alveolar saturated phosphatidylcholine (Table III). However, treatment with the 0.1 mg/kg betamethasone regimen decreased the total lung surfactant pool ($p < 0.01$). In the surfactant-treated groups there were no differences in air space or total lung surfactant pool sizes.

Protein accumulation. The percent recovery of intravascular ^{131}I-albumin in the alveolar wash and total lung was used as a measurement of the accumulation of intravascular protein in the alveolus and lung tissue, with a higher percent recovery indicating greater protein leak into the lung (Fig. 2). In the animals not treated with surfactant, the 0.1 mg/kg dose of betamethasone decreased protein leak in both the airspaces

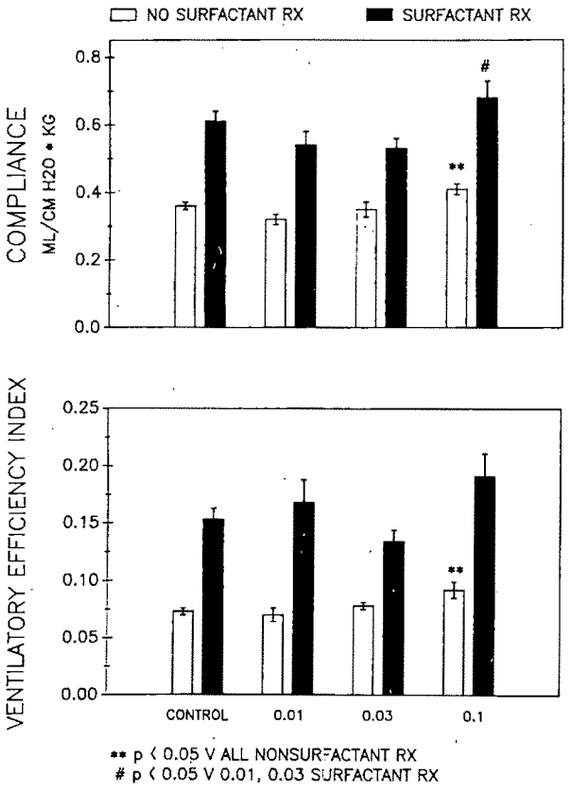

Fig. 1. Compliance *(upper)* and ventilatory efficiency index *(lower)* for corticosteroid treatment regimens with and without surfactant therapy. In this and subsequent figures 0.01, 0.03, and 0.1 refer to the doses of betamethasone in milligrams per kilogram. In the absence of surfactant therapy both compliance and ventilatory efficiency index were improved with the 0.1 mg/kg dose of betamethasone. With surfactant therapy the rabbits treated with 0.1 mg/kg were more compliant than those treated with 0.01 and 0.03 mg/kg.

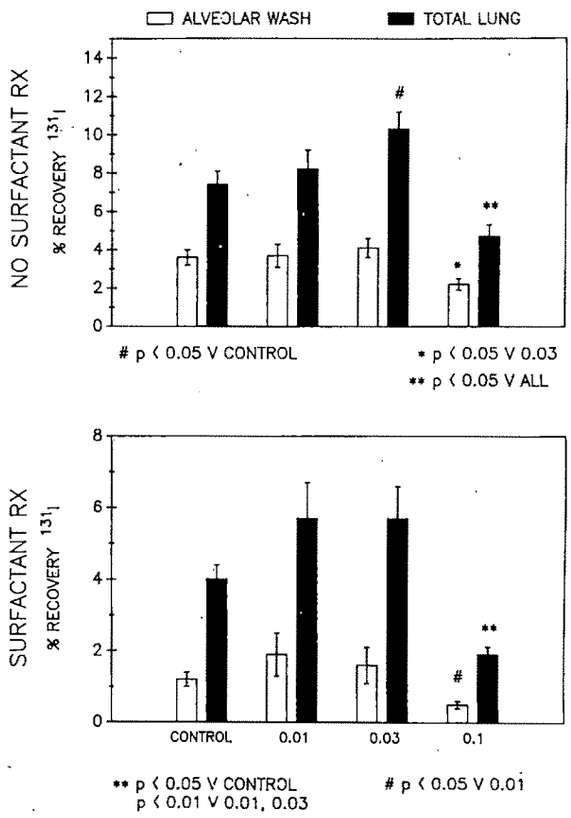

Fig. 2. Percent recovery of ^{131}I-albumin from the alveolar wash and total lung. In the absence of surfactant therapy *(upper)*, the 0.1 mg/kg dose had less total lung protein leak than the other doses. The 0.03 mg/kg dose had higher alveolar wash protein leak than the 0.1 mg/kg dose and higher total lung protein leak than the control animals. With surfactant therapy *(lower)* the 0.1 mg/kg dose had less total lung protein leak than the other doses and less alveolar wash leak than the 0.01 mg/kg dose.

Table III. Saturated phosphatidylcholine

Group	Control	*Betamethasone*		
		0.01 mg/kg	*0.03 mg/kg*	*0.1 mg/kg*
No surfactant treatment				
Alveolar wash (μmol/kg)	0.54 ± 0.05	0.49 ± 0.06	0.51 ± 0.07	0.45 ± 0.04
Total lung (μmol/kg)	59.0 ± 2.5	59.1 ± 2.9	60.0 ± 2.4	47.1 ± 2.5*
Surfactant treatment				
Alveolar wash (μmol/kg)	14.3 ± 2.2	13.2 ± 1.6	13.1 ± 2.2	13.7 ± 1.7
Total lung (μmol/kg)	80.6 ± 3.8	79.1 ± 3.6	78.8 ± 3.0	71.3 ± 3.4

*$p < 0.01$, versus all non-surfactant-treated groups.

(alveolar wash) and the total lung by 35% to 40% from the levels seen in the control animals, although this only reached significance with the total lung leak (total lung, $p < 0.05$; alveolar wash, $p < 0.1$). The protein leak in the 0.1 mg/kg group was also less than in the 0.03 and 0.01 mg/kg groups ($p < 0.05$). The alveolar wash leaks for the lower-dose steroid groups were similar to that of the control, but the total lung leak in the 0.03 mg/kg dose group was 40% higher than in the control ($p < 0.05$). Whereas the addition of surfactant treatment decreased the protein leak in all groups, similar relationships were found. The alveolar wash and total

lung leaks in the control group were twice those seen in the 0.1 mg/kg group, although again only the total lung leak was significant ($p < 0.05$). The protein leak into the air spaces and the total lung leak in both the lower-dose steroid groups were three times those of the 0.1 mg/kg group (total lung, $p < 0.01$ for both; alveolar wash, $p < 0.05$ for 0.01 mg/kg dose group).

The percent recovery of the intratracheal instilled ^{125}I-albumin reflects the movement of protein out of the airspaces, with a lower percent recovery indicating more movement, or leak, out of the lung (Fig. 3). In the non-surfactant-treated animals, the percent recovery was less in the 0.1 mg/kg group in the alveolar wash ($p < 0.01$ vs control) and in the total lung ($p < 0.05$ vs all). The addition of surfactant treatment increased the percent recovery in both the alveolar wash and the total lung and eliminated any differences between hormonal treatment groups.

Comment

This experiment illustrates the effects of antenatal corticosteroids in enhancing pulmonary maturation, as assessed in the preterm ventilated rabbit model. This model, with its varied end points, provides a more comprehensive picture of preterm lung function than can be obtained with in vitro studies, morphologic evaluations, or measurements of surfactant pool sizes and pressure-volume relationships in unventilated fetal lungs. In this model 0.1 mg betamethasone per kilogram maternal body weight improved overall lung function when given every 24 hours for 2 days before delivery. When comparison was made with the control group, this dosing regimen improved ventilation parameters (decreased peak inspiratory pressure and increased compliance) and gas exchange (increased ventilatory efficiency index), decreased protein leak into the lung, and improved protein clearance out of the airspaces and lung tissue. The lower doses of betamethasone did not have objective lung maturational effects. Most measurements were similar to those in the controls, the one exception being the incidence of pneumothorax in the non-surfactant-treated control animals. The lower doses of betamethasone may have induced subtle maturational changes in the lung tissue, which protected the airspaces from barotrauma at similar pressures. These changes were not evident in the more objective comparisons (protein leak, ventilatory efficiency index, or compliance) with the surviving control animals. In the surfactant-treated animals, which were ventilated at lower pressures, there were no differences between the low-dose steroid animals and the controls, including the incidence of pneumothorax. If anything, the lower doses tended to impair lung function, with greater degrees of protein leak and lower compliance.

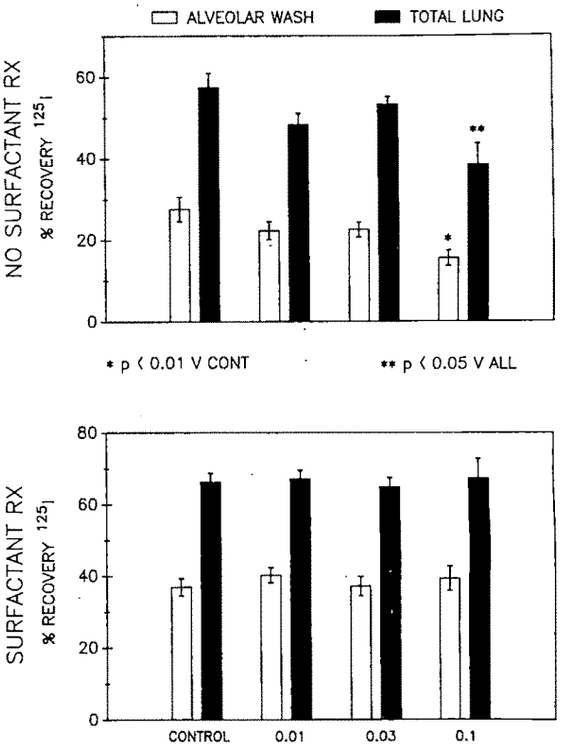

Fig. 3. Percent recovery of ^{125}I-albumin from alveolar wash and total lung. In absence of surfactant therapy *(upper)* improved protein clearance from alveolar wash (versus control) and total lung (versus all) was noted in 0.1 mg/kg group. No differences were noted in surfactant-treated groups *(lower)*.

Contrary to the perception that the beneficial effects of corticosteroids are due to stimulation of the surfactant system, these results were independent of surfactant effects. In the animals not treated with exogenous surfactant, the total lung saturated phosphatidylcholine pool was significantly less in the 0.1 mg/kg group. While studies in tissue cultures and unventilated fetal animals have shown increased surfactant synthesis with corticosteroids, our results are consistent with previous studies in the lamb and the ventilated preterm rabbit.[1, 2, 10] Since there is evidence suggesting the total lung saturated phosphatidylcholine pool may not accurately reflect the alveolar type II cell surfactant pool, the alveolar wash measurement may be a better marker of corticosteroid effects.[11] This tended to decrease with the highest dose of corticosteroid used. Corticosteroids may induce a more mature surfactant phospholipid and protein composition profile, which cannot be assessed by measuring only the saturated phosphatidylcholine pool.[12] We cannot comment on the degree of surfactant maturity in the high-dose steroid group, but the surfactant-independent effects of corticosteroids are further illustrated with exogenous surfactant treat-

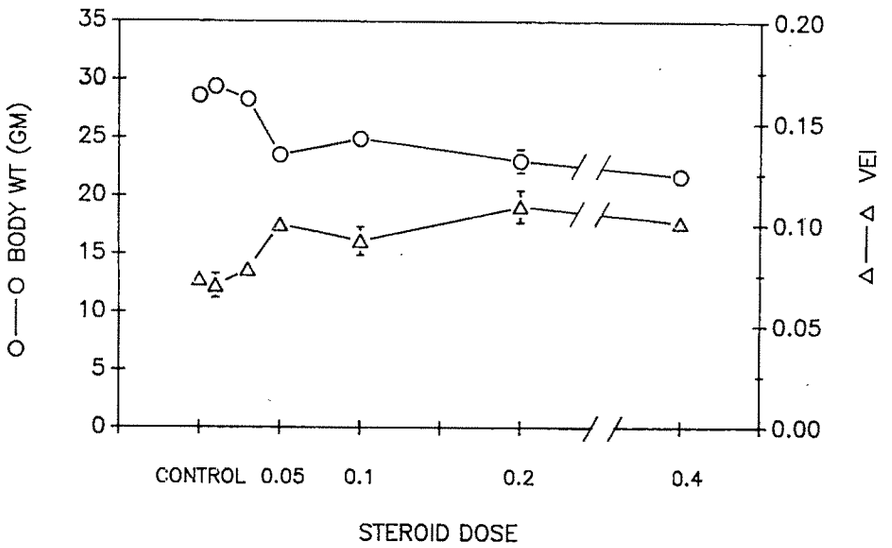

Fig. 4. Data from present study and that of Rider et al.[2] comparing body weight and ventilatory efficiency index for betamethasone doses ranging from 0.01 to 0.4 mg/kg. The 0.01 and 0.03 mg/kg doses had no effect on body weight or ventilatory efficiency index. The 0.05 mg/kg dose caused growth retardation and improvement in ventilatory efficiency index, with no changes in either parameter occurring with higher doses of betamethasone.

ment. The rabbits treated with 0.1 mg/kg betamethasone and surfactant were functionally more mature than the other surfactant-treated animals.

We could not separate the more objective pulmonary maturational effects of corticosteroids from the effects on growth retardation. Whereas lung maturation can be demonstrated in preterm mice and lambs without the detrimental impact on fetal growth, growth retardation and fetal loss are not uncommon in the preterm rabbit model.[2, 13, 14] The precise cause remains unclear. One possibility may be uteroplacental insufficiency as a result of placental degeneration. A second possibility is that the decreased growth is another direct effect of corticosteroids, via either depletion of glycogen stores or alterations in deoxyribonucleic acid synthesis and cell proliferation in sensitive preterm organs.[1]

When the results from this experiment are examined along with a previous investigation of corticosteroid treatments in rabbits, one sees a significant effect on fetal growth and lung maturation between doses of 0.03 and 0.05 mg/kg (Fig. 4).[2] Further enhancement of maturational effects, characterized in the figure by the ventilatory efficiency index, was not seen with doses exceeding 0.05 mg/kg. No growth effects were seen with 0.01 or 0.03 mg/kg, but similar degrees of growth retardation were seen beginning with the 0.05 mg/kg dose. These findings are consistent with the effects on fetal growth and pulmonary maturation being due to direct actions of corticosteroids and not secondarily due to placental degeneration. In the latter case one might expect varying degrees of uteroplacental insufficiency, growth retardation, and "stress-induced" lung maturation.

Corticosteroids act on target cells via specific receptors, which have been identified in fetal and adult lung tissue.[15] Whereas in vitro surfactant synthesis studies have demonstrated a linear relationship between glucocorticoid receptor occupancy and precursor incorporation, the few in vivo dose-response studies available are not so clear-cut.[16] Brehier et al.[17] found no effects on phosphatidic acid phosphatase activity in fetal rabbit lung with 0.025 mg betamethasone per kilogram of maternal body weight but similar induced enzyme activity with 0.1 and 0.25 mg/kg. Kaufman,[13] examining morphologic maturation in the preterm mouse lung, found maximal maturational changes with the lowest dose used (0.4 mg/kg) after 48 hours of therapy.

The observed dose effects add further credence to our suggestion that the beneficial effects derived from antenatal corticosteroids are not due primarily to the induction of surfactant synthesis. If this were the cause, by extrapolating from the in vitro studies, one would expect a somewhat linear dose response in overall lung function. Instead one sees an abrupt all-or-none response. The increase in compliance suggests alterations in the lung structure, perhaps changes in the collagen and elastin composition, as seen in the preterm lamb.[18] The function of the pulmonary vascular-alveolar barrier is improved, as evidenced by the decreased protein leak into and increased movement out of the airspaces,

as well as by the improved gas exchange suggested by the increase in ventilatory efficiency.

These findings offer some insight into the mechanism of action of corticosteroids in inducing preterm lung maturation. The impact of these agents on multiple sites that results in improved, more mature lung function should serve as a guideline for future investigation into the prevention and treatment of neonatal respiratory distress. It should also serve as a reminder that respiratory distress syndrome is not just surfactant deficiency.

Phospholipase C activity in microorganisms associated with reproductive tract infection

James A. McGregor, MDCM,[a] David Lawellin, PhD,[b] Amalia Franco-Buff, MA,[b] and James K. Todd, MD,[b]

Denver, Colorado

Phospholipase C (lecithinase or phosphatidylcholine phosphorylase) catalyzes the hydrolysis of lecithin into phosphorylcholine and 1,2-diglyceride. Bacterial production of phospholipase C may damage reproductive tract tissues by both direct and indirect mechanisms. Use of the synthetic substrate p-nitrophenylphosphorylcholine polspholipase C activity was determined in 204 isolates representative of those found in female genital tract. Multiple aerobic (28%) and anaerobic (28%) reproductive tract microorganisms showed phospholipase C activity. Phospholipase C–producing isolates included strains of *Bacteroides fragilis*, *B. bivius*, *B. thetaiotaomicron*, *Gardnerella vaginalis*, and group B streptococcus. Phospholipase C activity was heterogenous; not all isolates that belong to a particular species showed activity. Phospholipase C production may be a possible virulence factor produced by a number of microflora commonly implicated in various reproductive tract infections or conditions, as well as in some instances of preterm birth. (Am J Obstet Gynecol 1991;164:682-6.)

Key words: Phospholipase C, bacteria, reproductive tract, virulence factor, preterm birth

Phospholipase C (lecithinase or phosphatidylcholine phosphorylase) catalyzes the hydrolysis of lecithin into phosphorylcholine and 1,2-diglyceride.[1] Bacterial phospholipase C was first described as α-toxin of *Clostridium perfringens*, and is well known as the lethal, hemolytic, and dermonecrotic factor responsible for the tissue destruction associated with this organism.[1] Phospholipids constitute the fluid matrix of most biologic membranes and phospholipid-hydrolyzing enzymes occur naturally in mammaliam and bacterial cells.[1, 2] Interest has been focused on phospholipase C as a possible bacterial virulence factor capable of mediating cell, tissue, organ, and whole organism toxic effects.[2-4]

Of special interest in reproductive medicine is the action of phospholipase C on lecithin to produce 1,2-diglyceride, which may further serve as substrate for production of arachidonic acid.[5] Arachidonic acid serves as substrate for the production of prostaglandins, thromboxanes, leukotrienes, and other eicosanoids. These biologically active substances play important roles in parturition, embryo implantation, coagulation, and inflammation. Phospholipase C may also directly disrupt cell integrity and cause release of biologically active cell contents into local tissues. Phospholipase C is thus a bacterial virulence factor that may cause both direct and indirect reproductive tract cell and tissue damage.

Numerous bacteria produce phospholipase Cs. Microorganisms in which phospholipase C production is extensively characterized include *C. perfringens*, *C. novyi*, *Staphylococcus aureus*, *Bacillus cereus*, and a number of strains of *Acinetobacter*, *Pseudomonas*, and *Proteus*.[1] Other organisms known to produce phospholipase C include a variety of other clostridial species, *Escherichia coli*, *Listeria monocytogenes*, *Ureaplasma urealyticum*, *Candida albicans*, *Serratia marcescens*, *Flavobacterium* species, a number of other *Enterobacteriaceae* and *Flavobacterium*, and several marine bacteria.[1-6] Production of phospholipase C has been suggested to be the crucial pathogenic mechanism among *Pseudomonas* strains that cause urinary tract infection[4] (i.e. phospholipases differ in details of their stereospecificity, optimum substrates, and growth conditions.[1, 2]). Until recently, such variability and the contamination of available substrates made examination for phospholipase C activity impractical. Kurioka's[7] development of the synthetic chromogenic substrate p-nitrophenyl-phosphorylcholine allows for reliable screening and measurement of phospholipase C activity produced by a variety of microorganisms grown in defined conditions.[4, 8]

Large collections of microorganisms of interest in human disease have not been systematically examined for phospholipase C activity. As part of a series of stud-

ies to determine the extent, sources, and possible importance of phospholipase C in reproductive tract infections in women, we evaluated phospholipase C activity in a collection of aerobic and anaerobic microorganisms recovered from patients with chorioamnionitis, postpartum infection, or acute salpingitis.

Material and methods

Cultures. Reproductive tract test microorganisms (128 aerobic and 76 anaerobic, Tables I and II) were obtained from 50 women at University Hospital, Denver, Colorado, who underwent microbiologic evaluation for postpartum endometritis, acute salpingitis, or chorioamnionitis. Aerobic and anaerobic cultures were obtained from endometrium with a sterile double-lumen collecting device after cleansing the cervix. Endocervical and fetal membrane (fetal side) cultures were obtained with sterile cotton swabs. Aerobic and anaerobic cultures were transported promptly to the microbiologic laboratory with Culturette collection tubes (American Scientific Products, McGaw Park, Ill.) or anaerobic specimen collection tubes (Vacutainer collection tubes, Becton Dickinson, Rutherford, N.J.), respectively.

Predominant aerobic (up to three) and anaerobic (up to two) isolates from each patient were selected for testing. Because of their importance in nonhuman reproductive tract infection, strains of *Brucella melitensis* and *Brucella suis* were obtained from previously collected and stored blood culture specimens. Otherwise, isolates were identified to a species level with standard techniques and maintained in glycerol at −70° C until reculturing on appropriate media and establishing purity before testing. Mycoplasma and chlamydia were not evaluated.

Cultures of aerobic organisms were grown overnight (18 hours) in tryptose minimal growth media while being agitated at 250 rpm on a reciprocating shaker (Gyrotory Shaker, model G2, New Brunswick Scientific, Edison, N.J.) at 37° C in 10% carbon dioxide. Anaerobic organisms were grown for 24 hours or until visible growth occured in tryptose minimal growth media within a Gas Pack (BBL Microbiology Systems, Cockneysville, Md.) at 37° C without agitation. Cultures were then adjusted to a final optical density of 0.1 at 590 nm before incubation with p-nitrophenylphosphorylcholine. Clinical findings and measurements of vaginal fluid phospholipase C activity were not correlated with microbiologic findings in this study.

Supplies. p-Nitrophenylphosphorylcholine was obtained from Sigma Chemical Company, St. Louis, Mo. Tryptose minimal growth media was used as media throughout and was prepared locally. Plastic microtiter plates were used as incubation vessels for 90 μl of tryptose minimal growth media mixed with 10 μl supernatant of test organisms, prepared to a concentration of 0.100 optical density at 590 nm. A Titertek microtiter plate reader (Flow Laboratories, Rockville, Md.) was used as described previously.[4]

Enzyme assay. Ten μl of p-nitrophenylphosphorylcholine was added to each 100 μl of inoculated tryptose minimal growth media in sterile microtiter plates and read on a Titertek Mutiskan reader at 405 nm before incubation. The plates were sealed and incubated at 37° C for ten hours (aerobic organisms) or 24 hours (anaerobic organisms) without agitation. After incubation, the wells were reread with the microtiter plate reader. Controls included tryptose minimal growth media with or without 10 μl of p-nitrophenylphosphorylcholine. *Pseudomonas aeruginosa,* prototrophic strain PA01, whose metabolism in tryptose minimal growth media and phospholipase C action are established, was used as a positive control.[4-7] All tests were done in duplicate. Tests were interpreted as indicative of phospholipase C activity if both test postincubation colorimeter readings exceeded controls by 50%.[6]

Results

The 57 of 204 test specimens (28%) that showed phospholipase C activity are tabulated in Tables I and II. All PA01 prototroph stains of *P. aeruginosa* showed

phospholipase C activity. Previously documented phospholipase C activity was confirmed in our clinical isolates of *P. aeruginosa*, *Proteus mirabilis*, *Proteus vulgaris*, *E. coli*, *S. marcescens*, *C. albicans*, and *Klebsiella pneumoniae*. On the other hand, our test isolates of *S. aureus* and *L. monocytogenes* did not show phospholipase C activity with p-nitrophenylphosphorylcholine substrate when grown in tryptose minimal growth media. Among anaerobic test isolates, microorganisms not previously examined or known for phospholipase C production include strains of *Staphylococcus epidermidis*, group B streptococcus, *Streptococcus mutans*, *Streptococcus faecalis*, and a nonhemolytic streptococcus. Anaerobic test organisms showing phospholipase C activity included a variety of *Bacteroides* species, including *Bacteroides thetaiotaomicron*, *Bacteroides fragilis*, *Bacteroides melaninogenicus*, *Bacteroides bivius*, *Bacteroides distasonis*, and *Bacteroides vulgatus*. Other organisms that showed phospholipase C activity included *Peptostreptococcus anaerobius* and *Fusobacterium mortiferum*. Anaerobic test organisms generally exhibited less phospholipase C activity than did aerobic bacteria under test conditions.

There was heterogenity of phospholipase C production within multiple isolates of the same species. Among species of test bacteria that showed phospholipase C production, 49% of aerobic and 42% of anaerobic test isolates showed activity. Because optimum culture and incubation circumstances for showing phospholipase C activity were not determined for each microbial species or test isolate, it is likely that a greater number of isolates may have shown phospholipase C activity if tested in more favorble test conditions or in various in vivo settings.[9] Several organisms commonly found in the genital tract could not be adequately grown in supplemented peptone broth and were not evaluated.

Comment

Phospholipase C activity occurs in a variety of anaerobic and aerobic microorganisms commonly isolated from various body sites in both health and disease. Addition of these newly noted phospholipase C–producing microorganisms to the list of bacteria previously recognized as producing phospholipase C suggests that a wide assortment of reproductive microorganisms is capable of phospholipase C production. Heterogeneity of phospholipase C production among genetically well-defined bacterial strains has been previously noted.[1-4]

Bacterial production of phospholipase C within the reproductive tract may damage the host in several ways. phospholipase C–mediated cell membrane hydrolysis may cause complete lysis of affected cells. Any cell may be disrupted, as is noted in the instance of *C. perfringens* septicemia. Bacterial phospholipase Cs may also act as hemolysins (*S. aureus* α-toxin). Phospholipase C may also mediate host damage by less direct mechanisms. Phospholipase C cell membrane hydrolysis, which does not necessarily cause cell lysis, releases phosphatidylcholine and 1,2-diglycerides. As noted, diglycerides can be converted into arachidonic acid by diglyceride lipase. Damaged, the remaining cell membrane is opened to other phospholipases that may further release arachidonic acid from exposed phospholipids. Lapetina et al.[10] suggest that phospholipase C may increase arachidonic acid production by converting phosphatidylinositol into phosphatidic acid, which is readily acted on by phospholipase A_1 to produce arachidonic acid.

Phospholipase C produced by various reproductive tract microorganisms may predispose patients to preterm birth by increasing local tissue concentrations of arachidonic acid and subsequent metabolites. Because prostaglandins and other eicosanoids are not stored within cells, availability of arachidonic acid is a primary rate limiting step in their production.[11] Pathophysiologically increased reproductive tract tissue levels may have numerous untoward effects. Prostaglandins E_2 and $F_{2\alpha}$ play primary roles in the initiation and maintenance of labor.[12] Both these substances may be used to pharmacologically initiate labor and abortion.[12]

Alteration of reproductive tract eicosanoid metabolism by phospholipase C–producing microorganisms may predispose or mediate labor less directly. Prostaglandin E_1 and thromboxane A_2 are chemotactic factors that incite and direct inflammatory cell migration.[11] Thromboxane A_2 is such a potent chemotactic sub-

stance that neutrophils may clog small vessels and impair microcirculation and tissue viability.[11] Neutrophils and macrophages in vessels and tisues may release damaging substances, such as collagenases, elastases, cathepsins, phospholipases, and free oxygen radicals that can further damage adjacent cells and extracellular connective tissue.[11] Release of such virulence factors within the cervix or lower uterine segment may be associated with direct collagenolysis and cervical softening or ripening.[13] Any of these substances may damage phospholipase A_2-laden decidual cells.[14] When disturbed, decidual cells can release phospholipase A_2 within the uterus, and act as a further stimulus to labor.[12]

Recent observations suggest that locally increased phospholipase C concentrations may further alter reproductive tract homeostasis at subcellular levels. Evidence now suggests that unsaturated diacylglycerols, released by endogenous or exogenous phospholipase C, act as physiologic agonists for activation of protein kinase C.[15-17] These effects may be blocked by phospholipase C inhibitors.[18] Friedman et al.[19, 20] first suggested that protein kinase C appears identical to epidermal growth factor receptor. This receptor is also activated by phorbol diesters.[18-20] Tumor-promoting phorbol diesters are, by themselves, noncarcinogenic but induce tumor formation when administered after subthreshold doses of a carcinogen.[21] Activation of protein kinase C by diglycerides, phorbol esters, and epidermal growth factor can induce multiple cell changes (i.e., morphologic transformation; altered prostaglandin, phospholipid, and protein synthesis; increased superoxide production; and loss of cell surface fibronectin and other cell surface proteins).[16-20] The bee phospholipase melittin promotes the same cellular effects as do phorbol esters.[21] It is of interest that recent work[22, 23] suggests that the oncogene *erb*B codes for a portion of epidermal growth factor receptor. The finding of this link between epidermal growth factor receptor gene and *erb*B underscores prior knowledge that receptors of other growth-stimulating agents, such as insulin and platelet-derived growth factor, are also kinases.[24] Growth modulating substances such as epidermal growth factor and other factors that activate cellular kinases are increasingly implicated in controlling the onset of human parturition.

These observations suggest that products of phospholipase C activity are basic to multicellular life and are consistent with activation of a protein kinase, most likely by enzyme phosphorylation in the presence of calcium.[15, 16, 18] Activation of cell protein kinase by diacylglyceride products of phospholipase C may occur in tissues normally exposed to phospholipase C–producing microorganisms, as well as those subject to phospholipase C activity during localized or systemic infection. Acute exposure to nonlethal concentrations of phospholipase C may alter both tissue and host defense cells in, as yet, undetermined ways. More prolonged exposure to bacterial phospholipase C produced by microorganisms may allow for an effect similar to those of phorbol esters in promoting transformation of cells also exposed to a carcinogen, thus possibly increasing risks of neoplasia within the lower genital tract.

Substantiation of in vivo bacterial phospholipase C production as a virulence factor within the reproductive tract can allow for the possibility of specifically mitigating phospholipase C activity. A variety of lower alcohols and univalent anions (Cl-, I-, and others) inhibit phospholipase C and other enzymes produced by *Bacillus cereus*.[22, 23] A synthetic compound, 2,3-distearoyioxyprolyl(dimethyl)-B-hydroxyethylammonium acetate, and the antimicrobials bleomycin and polymyxin B, inhibit release of phospholipase C, as do serine esterase inhibitors.[24, 25] Antibody to phospholipase C appears effective during in vitro neutralization tests, but no in vivo tests have been performed.[26] Addition of phosphate in vitro inhibits phospholipase C in a variety of *Pseudomonas* species.[7] More practically, subinhibitory levels of antimicrobials, such as clindamycin, inhibit production of extracellular bacterial products, including lipase production by *Propionibacterium acnes*. Treatment with even subtherapeutic amounts of selected antimicrobials that inhibit production or release of phospholipase C may be of benefit. Such observations allow speculation that microbial virulence factors such as phospholipase C may be inactivated or ameliorated by specific therapy if phospholipase C can be shown to be of significance in reproductive tract infection. Studies correlating vaginal concentrations of phospholipase C and pregnancy outcome are under way.

In summary, aerobic and anaerobic microorganisms frequently isolated from patients with reproductive tract infections were examined for phospholipase C production with p-nitrophenylphosphatidylcholine as substrate. Phospholipase C production was documented in vitro in numerous cervicovaginal aerobic and anaerobic microorganisms commonly involved in ascending reproductive tract infection (Tables I and II).

The action of nitric oxide in the perfused human fetal-placental circulation

Leslie Myatt, PhD,[a, b, c] Anthony Brewer, BS,[a] and Diane E. Brockman, MS[a]
Cincinnati, Ohio

Nitric oxide is thought to be the endogenous endothelium-derived relaxing factor. We investigated the effects of compounds that either generate nitric oxide intracellularly or inhibit its action on the vasculature of the human placental villus. Addition to perfusion medium of methylene blue (10^{-5} mol/L), which is an inhibitor of activation of guanylate cyclase by nitric oxide, significantly increased perfusion pressure of the fetal-placental circulation over a range of flow rates (1 to 10 ml/min) compared with the perfusion pressures seen in the absence of methylene blue. This suggests basal release of nitric oxide may contribute to maintenance of resting vascular tone. Both glyceryl trinitrate (10^{-9} to 5×10^{-6} mol/L) and S-nitroso-N-acetylpenicillamine (10^{-8} to 10^{-4} mol/L), which generate nitric oxide intracellularly, were able to significantly vasodilate the fetal-placental circulation preconstricted with the thromboxane mimetic U46619 (1 to 5×10^{-8} mol/L) in a concentration-dependent manner. These compounds had no effect in the absence of the vasoconstrictor. Thus it appears that the placental villus vascular tree has the ability to both generate and respond to nitric oxide. (Am J Obstet Gynecol 1991;164:687-92.)

Key words: Nitric oxide, endothelium-derived relaxing factor, placenta, blood flow

Furchgott and Zawadski[1] first showed the necessity for the presence of endothelial cells in the relaxation of isolated rabbit aorta and other arteries induced by acetylcholine or other muscarinic agonists. A large number of agents are now known to give endothelium-dependent relaxation of blood vessels resulting from the release of a labile nonprostanoid endothelium-derived relaxing factor or factors.[2] Endothelium-derived relaxing factor acts by means of stimulation of guanylate cyclase in vascular smooth muscle to produce cyclic guanosine monophosphate, which causes relaxation. It is of interest that flow-induced shear stress also stimulates endothelium-derived relaxing factor release and endothelium-dependent relaxation occurs in resistance vessels as well as in arteries. During the same time period that endothelium-derived relaxing factor was first described, Ignarro et al.[3] found that nitric oxide caused a rapid transient relaxation of bovine coronary artery. Nitric oxide also activated soluble guanylate cyclase from coronary artery. The findings that both endothelium-derived relaxing factor and nitric oxide stimulate guanylate cyclase and that their action is inhibited by methylene blue, hemoglobin, and superoxide anion suggest a common identity. There is, however, evidence of other relaxing factors, including an endothelium-derived hyperpolarizing factor in some vessels.

In the absence of autonomic innervation, blood flow in the human fetal-placental circulation appears to be regulated by humoral agents or by some autocrine mechanism in the fetal-placental vasculature. We previously showed[4, 5, 6] that angiotensins I, II, and III and the thromboxane A_2 mimetic U46619 are vasoconstrictors in this circulation in vitro, whereas the vasodilator prostaglandins PGD_2, PGE_1, and $6\beta PGI_1$ (a prostacyclin analog) can attenuate angiotensin II–induced vasoconstriction. Van de Voorde et al.[7] showed that human umbilical blood vessel endothelial cells release an endothelium-derived relaxing factor in response to histamine but not acetylcholine, and Chaudhuri et al.[8] reported that both human umbilical artery and placental chorionic plate arteries were relaxed by substances that release nitric oxide. We decided therefore to establish whether the resistance vessels of the villous tree in human placental cotyledons were responsive to nitric oxide.

Material and methods

Placentas were collected immediately after normal vaginal delivery or elective cesarean section and transported to the perfusion laboratory in the labor and delivery area. A suitable third or fourth order chorionic artery and corresponding vein of an intact cotyledon were cannulated as previously described (Glance et al.,[4]

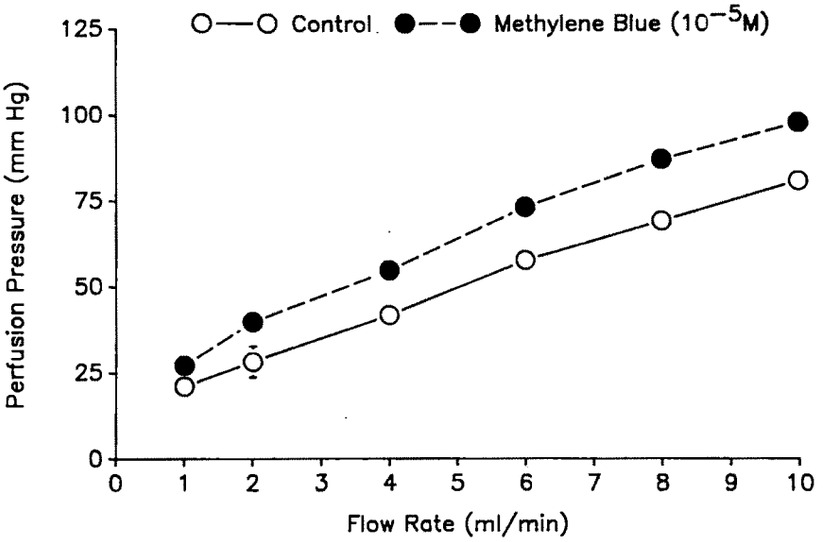

Fig. 1. Effect of methylene blue on perfusion pressure at differing flow rates. Perfusion pressure of fetal-placental circulation at varying flow rates (1 to 10 ml/min) was measured in same placenta in presence or absence of methylene blue (10^{-5} mol/L) in perfusion medium. The differences in perfusion pressure in presence or absence of methylene blue and at each flow rate were compared by two-way analysis of variance with repeated measures over two factors. Mean ± SEM of five separate experiments are shown (except where shown, SEM is smaller than size of symbol). There was significant difference between perfusion pressures obtained at each flow rate ($p < 0.005$) in either the presence or absence of methylene blue. Perfusion pressures in presence of methylene blue were significantly different from those in absence of methylene blue ($p < 0.005$) at each flow rate except 1 ml/min.

1984) at a point immediately before passage of the vessels through the chorionic plate. The maternal intervillous space was cannulated with two butterfly needles inserted through remnants of the spiral arteries in the basal plate. The effluent from the intervillous space was collected by gravity into an acrylic plastic cone over which the cotyledon was placed, maternal surface downward. Perfusion medium was tissue culture medium 199, containing 5% polyvinylpyrrolidone 40 and 0.1% bovine serum albumin as oncotic agents with 20 IU/ml heparin and 48 μg/ml gentamicin added, pH 7.4 with bicarbonate. Medium was gassed with 95% oxygen and 5% carbon dioxide at 37° C. Flow rates were 4 ml/min fetal and 10 ml/min maternal, except where stated. Lateral pressure was measured on fetal and maternal inflow lines adjacent to the point of cannulation. Data on pressure, inflow, and outflow Po_2 and pH were sampled every second and stored on an IBM PS2 computer system with Asystant Plus software (Asyst Technologies, Rochester, N.Y.).

In a series of experiments in which the involvement of a putative nitric oxide–mediated mechanism on flow-dependent vasodilation was investigated, the flow rate in the fetal circulation of the placenta was changed at 10-minute intervals in the order 4, 2, 4, 6, 8, 10, 4 ml/min. Perfusion pressure was measured throughout the experiment and maternal flow rate was kept constant at 10 ml/min. Then in the same placenta, methylene blue (10^{-5} mol/L) was added to both maternal and fetal perfusates and after a 20-minute period of equilibration, the flow rate was again changed at 10-minute intervals in the order 4, 2, 4, 6, 8, 10, 4 ml/min and perfusion pressure recorded. Both circulations were perfused with methylene blue throughout this entire sequence of flow-rate changes. In some experiments, perfusate was subsequently changed back to medium not containing methylene blue and, after an equilibration period of 20 minutes, the series of changes in flow rates was again performed and perfusion pressure measured at each flow rate.

The effects on fetal-placental perfusion pressure of agents that generate nitric oxide intracellularly was studied next. The thromboxane-mimetic U46619 was added to the fetal-placental perfusate in a final concentration range of 1 to 5 × 10^{-8} mol/L to increase fetal-placental perfusion pressure to 100 to 150 mm Hg at a flow rate of 4 ml/min. Then glyceryl trinitrate was injected as a 2 ml bolus in perfusion medium directly into the fetal inflow line, via an injection valve, over a range of concentrations (10^{-9} to 5 × 10^{-6} mol/L). Fifteen minutes were allowed to elapse between each infusion of glyceryl trinitrate to allow perfusion pressure to return to resting levels. The perfusates of both fetal and maternal circulations were then changed to fresh medium containing methylene blue (10^{-5} mol/L). A 20-minute period of equilibration

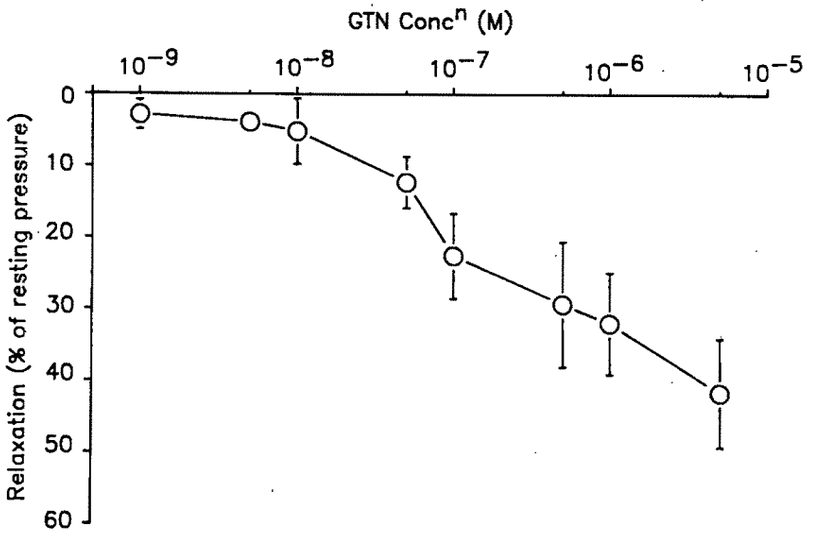

Fig. 2. Effect of glyceryltrinitrate *(GTN)* in U46619-induced vasoconstriction in the fetal-placental circulation. Fetal-placental circulation was preconstricted with U46619 (1 to 5 × 10^{-8} mol/L) and effect of bolus infusion of glyceryl trinitrate (10^{-9} to 5 × 10^{-6} mol/L) on perfusion pressure established. Vasodilation to glyceryl trinitrate is expressed as percentage of relaxation from resting perfusion pressure. Mean ± SEM of four separate experiments is shown. Analysis of variance showed significant concentration-dependent vasodilation ($p < 0.005$) with addition of glyceryl trinitrate.

was allowed before the concentration of glyceryl trinitrate that gave the greatest relaxation was reinjected into the fetal-placental circulation and the response measured. The experiments described with glyceryl trinitrate were subsequently repeated in different placentas using S-nitroso-N-acetylpenicillamine, 10^{-8} to 10^{-4} mol/L, as an alternative agent to generate nitric oxide intracellularly. After establishment of the concentration-dependent relaxation in these experiments, pyrogallol (10^{-4} mol/L) was added to both maternal and fetal perfusates to generate superoxide anion. After a 20-minute equilibration with pyrogallol the concentration of S-nitroso-N-acetylpenicillamine found to give the greatest relaxation was reinjected and response measured.

All experiments were repeated in at least four separate placentas. U46619 was kept as a 10^{-3} mol/L stock in ethanol at −20° C and diluted before use; glyceryl trinitrate was kept as an aqueous solution at 10^{-3} mol/L at 4° C; and S-nitroso-N-acetylpenicillamine was stored in a desiccator at 4° C, solubilized in water before use, kept on ice, and used within 4 hours of preparation. The vasodilator response to glyceryl trinitrate or S-nitroso-N-acetylpenicillamine was expressed as percentage of relaxation from the resting perfusion pressure in each placenta. Analysis of variance with repeated measures was used to determine the significance in change in perfusion pressure on infusion of increasing concentrations of glyceryl trinitrate or S-nitroso-N-acetylpenicillamine. The differences in perfusion pressure in relation to flow in the absence or presence of methylene blue were analyzed by two-way analysis of variance with repeated measures over two variables (flow and the presence or absence of methylene blue). All procedures were approved by the University of Cincinnati College of Medicine Institutional Review Board.

Results

The relationship of perfusion pressure to flow in the fetal-placental circulation is shown in Fig. 1. At all flow rates except 1 ml/min, the perfusion pressure was significantly greater ($p < 0.005$) in the presence of methylene blue (10^{-5} mol/L) than that measured in the absence of methylene blue. The perfusion pressures at each flow rate were significantly different from each other ($p < 0.005$) in both the presence or absence of methylene blue. The increase in perfusion pressure on addition of methylene blue was rapid in onset (<5 minutes, data not shown). However, reversion to media not containing methylene blue was not accompanied by a reduction in perfusion pressure (i.e., the effect of methylene blue appeared irreversible).

Addition of U46619 (1 to 5 × 10^{-8} mol/L) increased perfusion pressure of the fetal-placental circulation. The resulting average resting pressure in the presence of U46619 before addition of glyceryl trinitrate or S-nitroso-N-acetylpenicillamine was 113 ± 12 mm Hg (mean ± SEM, $n = 11$). Bolus infusion of glyceryl trinitrate (10^{-9} to 5 × 10^{-6} mol/L) produced a significant ($p < 0.005$) concentration-dependent vasodilation of the U46619-constricted fetal-placental circulation (Fig. 2). The maximal vasodilation induced by

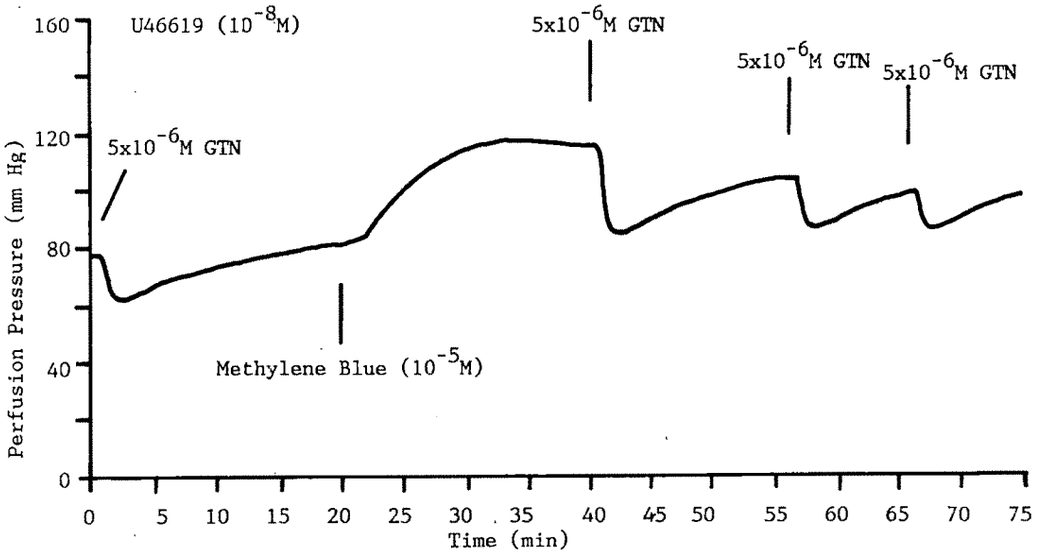

Fig. 3. Effect of methylene blue (10^{-5} mol/L) on glyceryl trinitrate–induced vasodilation. Vasodilator response to glyceryl trinitrate (5×10^{-6} mol/L) in fetal-placental circulation preconstricted with U46619 (10^{-8} mol/L) is shown in representative experiment before and after addition of methylene blue (10^{-5} mol/L) to perfusion medium. U44619 is present throughout.

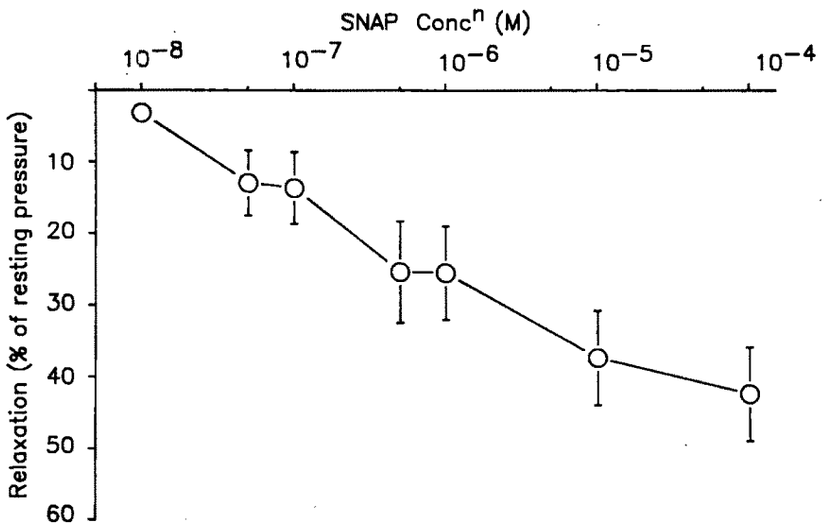

Fig. 4. Effect of S-nitroso-N-acetylpenicillamine *(SNAP)* on U46619-induced vasoconstriction in fetal-placental circulation. Fetal-placental circulation was preconstricted with U46619 (1 to 5×10^{-8} mol/L) and effect of bolus infusion of S-nitroso-N-acetylpenicillamine (10^{-8} to 10^{-4} mol/L) on perfusion pressure measured. Vasodilation to S-nitroso-N-acetylpenicillamine is shown as percentage of relaxation from resting perfusion pressure. Mean ± SEM of seven separate experiments is shown. Analysis of variance showed significant concentration-dependent vasodilation ($p < 0.005$) with addition of S-nitroso-N-acetylpenicillamine.

glyceryl trinitrate gave a decrease in perfusion pressure of 58 ± 19 mm Hg. After infusion of methylene blue (10^{-5} mol/L) into the fetal-placental circulation (in the continued presence of U46619) the subsequent response to glyceryl trinitrate was reduced, compared with the response before methylene blue (Fig. 3). However, the glyceryl trinitrate–induced vasodilation could not be completely abolished by methylene blue, even with the use of a higher concentration of 10^{-4} mol/L methylene blue (data not shown). Although the vaso-

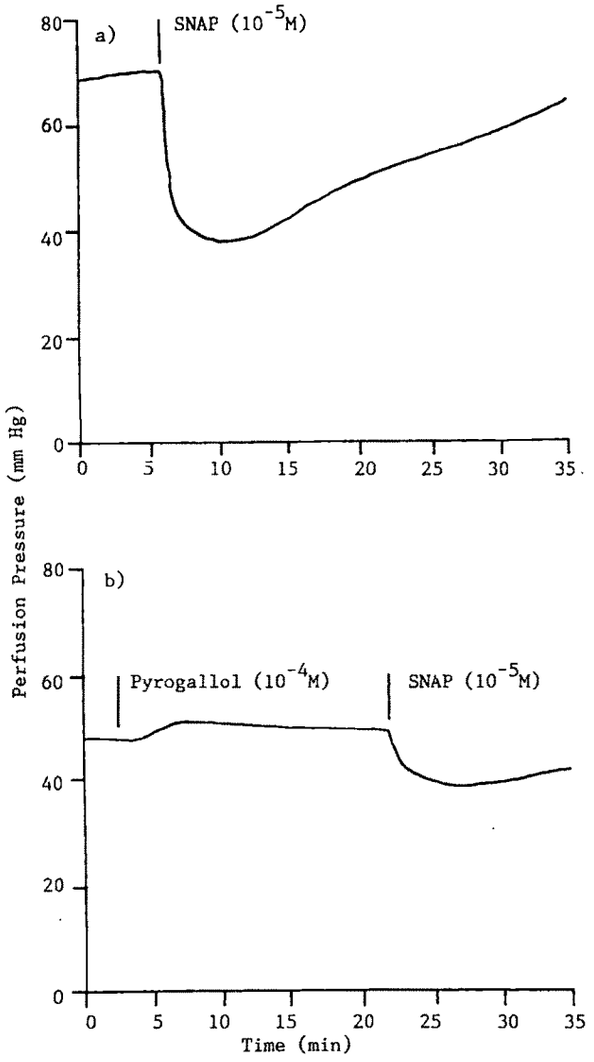

Fig. 5. Effect of pyrogallol (10^{-4} mol/L) on S-nitroso-N-acetylpenicillamine–induced vasodilation. Vasodilator response to S-nitroso-N-acetylpenicillamine (10^{-5} mol/L) in fetal-placental circulation preconstricted with U46619 (10^{-8} mol/L) is shown in representative experiment before (**a**) and after (**b**) addition of pyrogallol (10^{-4} mol/L) to perfusion medium. U46619 is present throughout.

dilator response was not abolished, it was seen to diminish with repetitive infusion of glyceryl trinitrate. The vasodilator response to 5×10^{-6} mol/L glyceryl trinitrate was 60 ± 11, 38 ± 11, and 22 ± 11 mm Hg for the first, second, and third infusions, respectively, after addition of methylene blue (n = 4 experiments). Control experiments (with the absence of methylene blue) showed a constant vasodilator response to repetitive infusion of glyceryl trinitrate, indicating that the diminishing response to glyceryl trinitrate in the presence of methylene blue was not a result of tachyphylaxis.

U46619-induced vasoconstriction of the fetal-placental circulation could also be significantly attenuated ($p < 0.005$) in a concentration-dependent manner by S-nitroso-N-acetylpenicillamine (10^{-8} to 10^{-4} mol/L, Fig. 4). Again, the relaxant effect of S-nitroso-N-acetylpenicillamine could be partially, but not completely, abolished by methylene blue (data not shown) or by perfusion of the fetal-placental circulation (Fig. 5) with pyrogallol (10^{-4} mol/L), which generates superoxide anion and thereby inactivates nitric oxide. The relaxation to 10^{-5} S-nitroso-N-acetylpenicillamine was 42.7 ± 13.1 and 19.8 ± 5.0 mm Hg before and after addition of 10^{-4} mol/L pyrogallol, respectively (n = 5 experiments). Neither glyceryl trinitrate nor S-nitroso-N-acetylpenicillamine was able to significantly relax the fetal-placental circulation perfused at 4 ml/min unless it had been previously constricted with U46619.

Comment

A wide variety of blood vessels have been studied for their ability to exhibit endothelium-dependent relaxation.[2] However, the vessels of the human fetal-placental circulation have not been rigorously investigated. Van de Voorde et al.[7] described the release of endothelium-derived relaxing factor from human umbilical blood vessels stimulated with histamine but did not show an action of that endothelium-derived relaxing factor on the umbilical vessels themselves. The human placental chorionic plate arteries were shown by Griggs and McLaughlin[9] not to relax to either A23187 or histamine, which stimulate endothelium-derived relaxing factor release from umbilical vessels, leading to the conclusion that these arteries had little ability to release endothelium-derived relaxing factor. However, these researchers did show that nitric oxide and sodium nitroprusside were able to relax the chorionic plate artery, findings confirmed by Chaudhuri et al.,[8] who showed relaxation of precontracted human umbilical or placental arteries by glyceryl trinitrate or S-nitroso-N-acetylpenicillamine, both of which generate nitric oxide intracellularly.

We have studied the action of nitric oxide in the placental villus vascular bed, which presumably is a major determinant of resistance in the fetal-placental circulation. It is clear that both glyceryl trinitrate and S-nitroso-N-acetylpenicillamine, which generate nitric oxide intracellularly,[10] are able to relax this vascular bed in a concentration-dependent manner when it has been preconstricted with the thromboxane mimetic U46619. The conclusion that these effects are mediated by nitric oxide is strengthened by our observations that methylene blue antagonizes the vasodilator effect. Methylene blue is an inhibitor of guanylate cyclase activation by nitric oxide.[11] We were unable to totally abolish the effect of glyceryl trinitrate or S-nitroso-N-

acetylpenicillamine even by increasing methylene blue concentrations to 10^{-4} mol/L. This is similar to the observations in other systems.[15] However, we did see a diminution of vasodilator response with increasing time of exposure to methylene blue that did not appear to be a result of tachyphylaxis. Similarly, pyrogallol, which generates superoxide anion and inactivates nitric oxide, was able to prevent the relaxant effects of glyceryl trinitrate or S-nitroso-N-acetylpenicillamine. Reduced hemoglobin acts as an inhibitor of nitric oxide released extracellularly by binding to it to form a nitrosylhemoprotein complex that cannot penetrate the cell membrane. In our hands, reduced hemoglobin (10^{-5} mol/L) infused into the fetal placental circulation did not affect the pressure-flow relationship (data not shown). Thus it appears that nitric oxide is not released extracellularly before action in the fetal-placental circulation.

In the absence of autonomic innervation the fetal circulation of the human placenta may be regulated by autocrine mechanisms, such as flow-induced vasodilation, or by humoral vasoactive agents. However, the mechanisms mediating these mechanisms have not been identified. We previously established the relationship of perfusate flow rate to perfusion pressure, and hence vascular resistance, in the perfused cotyledon and found that blockade of prostaglandin synthesis by meclofenamate had no effect on the flow-pressure relationship.[13] This suggested that a prostaglandin was not involved as a humoral vasodilator. We showed that perfusion of the isolated cotyledon with methylene blue (10^{-5} mol/L) was able to alter the perfusion flow-pressure relationship so that pressure and hence resistance was greater at all flow rates in the presence of methylene blue. This suggests that basal release of nitric oxide may contribute to maintenance of vascular tone in this circulation. In preliminary experiments with the use of a series of compounds that stimulate endothelium-derived relaxing factor release in other vascular beds, we were unable to show vasodilation of the fetal-placental circulation. The stimulus for the release of nitric oxide (i.e., endothelium-derived relaxing factor) in the perfused fetal-placental circulation may be flow or shear stress over the surface of endothelial cells. Increased release of endothelium-derived relaxing factor with increasing rate of flow (continuous or pulsatile) has been shown in canine femoral arteries.[14] The rapidity of the increase in resistance on addition of methylene blue to the fetal-placental circulation indicates that there may be basal release of nitric oxide, which may regulate vascular tone.

In summary, we showed that the fetal-placental circulation has the capacity to generate nitric oxide intracellularly and that nitric oxide can act as a vasodilator. There appears to be basal release of nitric oxide that may contribute to vascular resistance in this circulation.

We thank Dr. L. Ignarro and Dr. G. Chaudhuri for their kind gift of S-nitroso-N-acetylpenicillamine and the labor and delivery staff of University Hospital, Cincinnati, for their efforts in providing placental tissues.

Effects of acute hypermagnesemia on the threshold for lidocaine-induced seizures in the rat

Won W. Choi, MD, David S. Warner, MD, Daniel J. Monahan, MD, and Michael M. Todd, MD

Iowa City, Iowa

The effects of acute changes in plasma magnesium concentration on the threshold for lidocaine-induced seizures were evaluated in mechanically ventilated rats receiving 70% nitrous oxide and 30% oxygen. In experiment 1, male rats were intravenously administered either 0.9% sodium chloride (group I) or 5.0% magnesium sulfate to elevate plasma magnesium levels to 5.8 ± 0.1 (group II) or 10.5 ± 1.0 mg/dl (group III). In experiment 2, pregnant rats were intravenously administered either 0.9% sodium chloride (normomagnesemia) or magnesium sulfate, resulting in a plasma magnesium concentration of 7.8 ± 1.4 mg/dl. Thirty minutes later, a continuous intravenous infusion of lidocaine (2.3 mg/kg per minute) was begun in both experiments. Biparietal electroencephalographic activity was monitored continuously. At the onset of electroencephalographic seizure activity, arterial plasma magnesium and lidocaine concentrations were measured. In groups I and III (experiment 1), brain parenchymal magnesium was also assayed. There were no differences in plasma lidocaine concentrations (in experiments 1 or 2) between saline solution and hypermagnesemic groups at onset of seizures. Brain magnesium level was unaltered by magnesium sulfate infusion. We conclude that acute administration of magnesium sulfate alters neither brain magnesium level nor the plasma lidocaine concentration associated with onset of electroencephalographic seizures. (Am J Obstet Gynecol 1991;164:693-7.)

Key words: Anesthetic agents, lidocaine, brain seizures, electrolytes, magnesium, hypermagnesemia

Despite controversy regarding its mode of action,[1,2] magnesium sulfate has long been used for both the prevention and treatment of complications associated with pregnancy-induced hypertension.[3,4] In particular, magnesium sulfate is believed to play a therapeutic role in minimizing convulsant manifestations of this disorder. At the same time, patients treated with magnesium sulfate frequently receive large doses of local anesthetic agents to provide analgesia during obstetric procedures.[5,6] Despite this practice, little information is available about potential interactions between these drugs with respect to central nervous system or cardiovascular toxicity.[7] Thus this study was designed to examine the effects of acute intravenous administration of magnesium sulfate on the plasma lidocaine concentration necessary to induce electroencephalographic seizures in the rat.

Material and methods

Surgical preparation. With institutional Animal Care and Use Committee approved, 39 Sprague-Dawley rats (Amitech, Omaha, Neb.) (weight range, 300 to 450 gm) were used in these experiments. In all animals the surgical preparation was identical. Anesthesia was induced with 4% halothane and maintained with 0.8% halothane in 70% nitrous oxide in oxygen. A tracheostomy was performed and mechanical ventilation adjusted to maintain $PaCO_2$ between 38 to 40 mm Hg and PaO_2 between 80 to 120 mm Hg. A femoral artery was cannulated by means of surgical incision for monitoring arterial blood pressure and blood sampling, whereas the femoral veins were cannulated bilaterally for fluid and drug administration. *d*-Tubocurarine (0.6 mg) and heparin (50 IU) were administered intravenously. Needle electrodes were percutaneously inserted between the temporalis muscle and parietal bones bilaterally, and a reference electrode was placed in the nape of the neck to continuously monitor bipolar electroencephalographic activity (Grass Model 79D, Quincy, Mass.). Rectal temperature was controlled between 36.5° C and 37.5° C by surface heating or cooling. A 45-minute interval was allowed for surgical preparation. All wounds were infiltrated with 1.0% lidocaine, the halo-

thane was then discontinued and the lungs thereafter ventilated with 70% nitrous oxide in oxygen. Given these conditions, a 15-minute stabilization period was allowed before the following procedures.

Experimental design and protocol

Experiment 1. Male rats were allocated randomly to one of three groups. Group I ($n = 8$) received 0.9% sodium chloride intravenously (2 ml/hr). Group II ($n = 10$) received magnesium sulfate (5.0% dissolved in sterile water) intravenously to produce a plasma magnesium level of 5.0 to 7.0 mg/dl. This was achieved by bolus administration of magnesium sulfate (60 mg, 1.2 ml) over 2 minutes, followed by a continuous infusion of 2 ml/hr until termination of the experiment. Group III ($n = 7$) received magnesium sulfate (120 mg, 2.4 ml) over 2 minutes, followed by 100 mg/hr intravenously to produce a plasma magnesium concentration of 9.0 to 12.0 mg/dl. Thirty minutes after onset of the saline solution or magnesium sulfate infusions, a continuous intravenous infusion of 1.0% lidocaine (Astra, Westborough, Maine) in 0.9% sodium chloride was begun at a rate of 2.3 mg/kg per minute. The electroencephalogram was monitored continuously during this time. At the onset of electroencephalographic seizure activity, samples of arterial blood were taken and centrifuged to separate the plasma. Mean arterial pressure (MAP), arterial blood gas pH values, and rectal temperature were also recorded at this electroencephalographic end point. Plasma lidocaine concentration was measured by radioimmunoassay (lidocaine assay, Syva Co., Palo Alto, Cal.). Plasma magnesium concentration was measured by an automated chemistry analyzer (calmagite dye method).

In some rats (group I, $n = 5$; group III, $n = 5$), a thoracotomy was performed immediately after onset of seizures. Via the left cardiac ventricle, the brain was rinsed in situ with 0.9% sodium chloride for 1 to 2 minutes to minimize contamination from blood magnesium. The brains were then removed intact and fast frozen in *n*-pentane (−70° C). Brain parenchymal magnesium concentration was later analyzed by atomic absorption spectroscopy with the use of forebrain tissue for each rat.

Experiment 2. Pregnant rats (14 days' gestation) were subjected to a protocol similar to experiment 1. Rats were randomly assigned to one of two groups. Eight rats received 0.9% sodium chloride intravenously (100 mg/hr), whereas 6 rats were administered a 60 mg bolus of magnesium sulfate over 2 minutes followed by a 100 mg/hr intravenous infusion of 5.0% magnesium sulfate to produce a plasma magnesium concentration of 7.0 to 8.0 mg/dl. Thirty minutes after onset of the saline solution or magnesium sulfate infusion, a continuous intravenous infusion of lidocaine (2.3 mg/kg per minute) was begun. At the onset of electroencephalographic seizure activity, arterial blood was withdrawn for assay of plasma lidocaine and magnesium concentrations. MAP, arterial blood gas pH values, and rectal temperature were also recorded at the onset of seizures.

Data analysis. Because of lack of concurrence, results from the two experiments were evaluated separately. Data were analyzed by a one-way analysis of variance. Posthoc testing was performed to identify between-group differences (experiment 1) when indicated, by a significant F ratio with the use of the Newman-Keuls test. Values are expressed as mean ± SEM. Significance was assumed at $p < 0.05$.

Results

Experiment 1. Before lidocaine infusion, the three groups did not differ in weight, $PaCO_2$, PaO_2, pH, temperature, or MAP (Table I). The magnesium sulfate administered intravenously to groups II and III resulted in plasma magnesium levels of 5.8 ± 0.7 and 10.5 ± 1.0 mg/dl, respectively (Table II). Plasma lidocaine concentrations did not differ between groups at the onset of seizures, nor was there a difference in the total dose of lidocaine administered (Table II). Brain parenchymal magnesium concentrations were similar between groups I (720 ± 14 μg/gm, dry weight) and III (725 ± 12 μg/gm, dry weight) despite the mean plasma magnesium concentration being five times greater in group III (Fig. 1). MAP was comparable between groups before the lidocaine infusion, but was significantly decreased in group III at the onset of seizures, when compared with group I (Table II).

Experiment 2. The normomagnesemic and hypermagnesemic groups did not differ in weight, $PaCO_2$, PaO_2, pH, temperature, or MAP immediately before lidocaine infusion (Table I). Plasma magnesium concentration at the onset of seizures was increased in those animals receiving magnesium sulfate infusion (7.8 ± 1.4 mg/dl) when compared with those that received saline solution (2.0 ± 0.1 mg/dl). In contrast, plasma lidocaine concentrations did not differ between the two groups at the onset of seizures (Table III). At the same time, MAP was significantly decreased in the hypermagnesemic versus normomagnesemic rats (Table III).

Comment

Because the administration of magnesium sulfate is often considered a therapy for convulsive manifestations associated with pregnancy-induced hypertension, we hypothesized that it might also be associated with an increased tolerance of the central nervous system to lidocaine toxicity. Our initial experimental approach involved the use of male rats wherein two levels of hypermagnesemia were induced 30 minutes before intravenous infusion of lidocaine. In this case, the plasma

lidocaine concentrations associated with onset of electroencephalographic seizures were found to be similar to those previously reported for both rats and primates,[8, 9] but remained independent of plasma magnesium levels. Corresponding to this, brain parenchymal magnesium concentrations were similar between groups despite a fivefold increase in plasma magnesium level. We then proceeded to determine whether characteristics unique to pregnancy in the rat would produce a different result. Again the plasma lidocaine concentration present at the onset of seizures was unaffected by acute hypermagnesemia, indicating no anticonvulsant activity for this ion. Of note, however, in both male and pregnant rats, the presence of hyper-

*$p < 0.01$.

magnesemia was associated with significantly lower mean arterial blood pressures at the onset of electroconvulsive activity.

The magnesium ion is a ubiquitous regulator in the nervous system. Specifically, an anticonvulsant activity might be attributable to inhibition of excitatory afferents which use glutamate as a neurotransmitter,[10] where magnesium has been shown to be a noncompetitive antagonist at the postsynaptic conductance channels.[11] Nevertheless, in numerous other well-controlled models of laboratory-induced epilepsy, including bupivacaine hydrochloride toxicity[7] and penicillin-induced seizure foci (pretreatment or post treatment),[12, 13] acute infusions of magnesium sulfate have consistently failed to exhibit anticonvulsant activities.

Other work[14, 15] showed that the bioavailability of magnesium to the brain is severely limited, most likely by the blood-brain barrier. It therefore seems likely that the duration of hypermagnesemia (30 to 45 minutes) in our study was insufficient to allow substantial transport of magnesium to the brain parenchyma. This is consistent with results from other studies evaluating transfer of magnesium from blood to brain. For example, Opelt et al.[16] observed only a 21% increase in cerebrospinal fluid magnesium concentration in dogs over 5.5 hours, while plasma magnesium was held 4 to 5 times normal. In contrast, Chutkow[17] found an increase in cerebral spinal fluid magnesium level identifiable within minutes after an intraperitoneal injection of magnesium chloride into hypomagnesemic rats; however, the cerebral spinal fluid was found not to reflect the brain parenchyma, which lagged several hours behind in showing an increase in magnesium concentration. Given this information, Thurnau et al.[18] evaluated cerebral spinal fluid magnesium levels in parturient preeclamptic women after 4.5 or more hours of magnesium sulfate infusion and found a 19% increase in cerebral spinal fluid magnesium concentration as a result of that therapy.

Thus if magnesium sulfate were to act as an anticonvulsant, it appears as if at least several hours of hypermagnesemia would be necessary to effect events at the neuronal level. Consequently, laboratory investigations, including ours, that have used brief exposures to hypermagnesemia do not rule out the potential for this ion to exhibit anticonvulsant properties against local anesthetic toxicity under conditions of prolonged therapy. In contrast, to the extent that the blood-brain barrier is normal in patients with pregnancy-induced hypertension (a matter that remains under investigation[19]), acute administration of magnesium sulfate should not be expected to protect against local anesthetic neurotoxicity. However, on the basis of the above cited information, further investigation with chronic models of hypermagnesemia or with models that invoke a disrupted blood-brain barrier may yield different conclusions.

A final methodologic consideration requires attention, that being the use of nitrous oxide in our preparation. Nitrous oxide analgesia has been shown to elevate the lidocaine seizure threshold by about 50% in the cat.[20] However, because hypercapnia (which would be expected to accompany large systemic doses of lidocaine) has also been shown to alter lidocaine seizure thresholds,[21] we elected to create an environment where artificial ventilation would be humane and allow control of the background anesthetic and ventilatory state across all groups considered. In fact, during pilot studies in which halothane was continued throughout the lidocaine infusion, we were unable to elicit any convulsive manifestations of lidocaine toxicity. Therefore the background anesthetic, although constant across all groups, is relevant in the interpretation of these results.

In conclusion, when either male or pregnant female rats were rendered acutely hypermagnesemic by an intravenous infusion of magnesium sulfate, the neurotoxic arterial plasma lidocaine concentration was not altered when compared with that observed in normomagnesemic controls. When brain magnesium concentration was quantified, no increases resulting from a fivefold increase in plasma magnesium levels were observed. This data is consistent with the belief that acute administration of magnesium sulfate will not serve to increase the threshold for lidocaine-induced seizures.

Effect of subject height on the result for the fifty-gram oral glucose tolerance test

To the Editors: Over a 12-month period, 1099 unfasted women at 24 to 28 weeks[3] gestation were screened for gestational diabetes with the 50 gm oral glucose tolerance test.[1] All women with a venous blood glucose value >6.7 mmol/L at 1 hour were retested the following week with the standard 100 gm 3-hour oral glucose tolerance test. The proportion of positive screen results was 9.3%, whereas the prevalence of confirmed gestational diabetes was 1.1%.

Logistic regression analysis established that age, short stature, elevated pregnancy weight, and Asian race are all significant predictors of positive screen results (Table I). Parity, past history of miscarriage, and abortion were other factors assessed but found not significant. Selection of only the data of white women for logistic regression reaffirmed that age and short stature are significant variables associated with risk of positive screen results, whereas weight is only significant in the model when both age and height are included. The mean height and weight of the Asian group increase the relative odds of positive screen results by 25% in comparison with white women. This result cannot be attributed to excess weight because the Asian women have a significantly lower body mass index than that of white women (23.6 ± 3.1, $n = 176$ vs 26.5 ± 4.7, $n = 799$; $p < 0.001$). The body surface area for Asians is also significantly lower (1.54 ± 0.12 vs 1.75 ± 0.16; $p < 0.001$).

Whereas age[2] and Asian race[3] have been reported as important determinants of glucose intolerance, the effect of height and weight has not been cited. In the model developed (Table I) these variables are compensatory, with maximum and minimum effects for short-heavy and tall-light women, respectively. Because body surface area is closely related to height, the present findings imply that the 1-hour blood glucose level after the 50 gm glucose challenge may reflect both glucose mass use as well as glucose intolerance. In support of this statement it has been advocated that the oral glucose tolerance test be adjusted for body surface area.[4]

Administration of the glucose load in the unfasted state may also accentuate a dose-related effect.[5]

The overall importance of a dose-effect for the 50 gm oral glucose tolerance test is difficult to judge but highlights a potential source of test variation that is unrelated to glucose intolerance yet may still significantly influence the final result.

Methotrexate treatment of ectopic gestation and reproductive outcome

To the Editors: I read with interest the report by Stovall et al. (Stovall TG, Ling FW, Buster JE. Reproductive performance after methotrexate treatment of ectopic pregnancy. AM J OBSTET GYNECOL 1990;162:1620-4). There seems to be no doubt that medical treatment of early unruptured ectopic pregnancy offers an attractive alternative to both the patient and the clinician.

However, I am skeptical about whether methotrexate as a folic acid antagonist should be the preferable substance, especially in view of possible teratogenic or mutagenic effects. The authors stated in their report that congenital malformations in subsequent pregnancies seem to be unlikely. The data about the overall teratogenic effect in patients who have had previous exposure to methotrexate, however, are still not satisfactorily clarified. The available figures are based on treatment of gestational trophoblastic neoplasms, and therefore only small numbers of subjects have been analyzed. Although van Thiel et al.[1] indicated no increase in fetal wastage or congenital abnormalities in a series of 50 women, Ross[2] described a 16% spontaneous abortion rate and a 3% stillbirth rate in 58 women, and Walden and Bagshawe[3] reported a total of seven cases (4.4%) with major fetal abnormalities in a group of 159 women who had been previously treated for trophoblastic tumors. These data are derived from women

who were treated systemically, and for the most part, they conceived years after termination of methotrexate therapy.

Furthermore, methotrexate has been shown to be retained in the tissue of men for up to 8 months (probably bound to some receptors), and the persistence was not related to the initial dose.[4] Also, concomitant application of citrovorum rescue did not prevent fixation of methotrexate in the tissue of mice.[5] Therefore the recommended 2-month period for use of a contraceptive device to avoid at least direct teratogenic effects seems to be too short a period of time. Moreover, the possibility that recessive mutations can be induced has not been addressed by any of the recent studies. Most mutations are indeed recessive and therefore are not easily detected unless the trait is sex-linked and thus occurs with greater frequency in male offspring. Observation over several generations would be required to answer this question.

The fact that methotrexate provides a greater likelihood for survival than other therapeutic modalities in patients with a potentially lethal disease does not necessarily indicate its use in cases of tubal pregnancy, especially because more harmless substances, including hyperosmolar glucose solutions[6] or prostaglandins,[7] have also proved to be successful.

Reply

To the Editors: We thank Dr. Egarter for his interest in our work on methotrexate treatment of ectopic pregnancy and, in particular, his interest in our article. During the last several months much has been written and several different medical alternatives have been described for the treatment of unruptured ectopic pregnancy. These have included systemic methotrexate, laparoscopic or transvaginal injection of methotrexate, potassium chloride, hyperosmolar glucose, prostaglandins, or RU-486. To date, most experience is in the area of systemic methotrexate. We believe that it will be the agent of choice for this condition, especially in light of the nonlaparoscopic diagnostic approach[1] and refinement of the regimen to only a single dose of methotrexate without citrovorum recovery.[2]

Dr. Egarter is correct in his concern that the reproductive effects of methotrexate after treatment of ectopic pregnancy have not been fully established. However, the data to date with respect to gestational trophoblastic disease are reassuring. In addition, the duration of therapy and the total dose of methotrexate given are much less than those in patients with trophoblastic disease and therefore represent another piece of reassuring data. The data of Ross[3] do indeed show a 16% spontaneous abortion rate and a 3% stillbirth rate. He states that his data do not include other known risk factors for fetal wastage, such as maternal age, and therefore the results are speculative. In addition, a 16% spontaneous abortion rate is well within normal limits, depending on the time the gestation is documented. Kjer and Iversen[4] reported no increase in the spontaneous abortion rate after combination chemotherapy with methotrexate and actinomycin D. Hammond et al.[5] reported similar results in 29 pregnancies with no increase in either the spontaneous loss or the congenital anomaly rate. Finally, Rustin et al.[6] showed no increase of second tumors after cytotoxic chemotherapy in 457 long-term survivors who underwent treatment for choriocarcinoma or invasive mole.

No study to date has done a systematic evaluation with a control group to evaluate offspring of patients treated with methotrexate. However, the weight of the evidence would favor that methotrexate is not mutagenic and does not increase the spontaneous abortion or fetal loss rate.

We believe that methotrexate therapy for unruptured ectopic pregnancy will gain wide acceptance as the nonlaparoscopic protocol and the single-dose regimen are considered.

Predictive value: Symptoms of preterm labor

To the Editors: Preterm birth is the greatest single cause of neonatal morbidity and mortality in the United States,[1] and as such deserves a concerted effort directed toward its prevention.The well-known continuing efforts of Drs. Robert Creasy and Michael Katz to sensitize obstetricians to the problem of preterm labor are commendable.

However, their recent article, which describes early signs and symptoms of preterm labor (Katz M, Goodyear K, Creasy RK. Early signs and symptoms of preterm labor. AM J OBSTET GYNECOL 1990;162:1150-3) contains a deceptive probability error and draws conclusions that require disputation.

The probability error is in Table V of their article, the calculation of predictive values. The incidence of preterm birth nationwide in 1980 was 3.55%; among black women the rate was 6.77%.[2] The article does not describe the demographics of the study population, but to derive the values reported in the table the incidence of preterm labor would have to be 50%!

A basic rule of medical probability (epidemiology) is to ask the question: "Is my answer reasonable?" Acceptance of Table V would require one to believe, for instance, that 86% of pregnant patients with urinary frequency are in, or will develop, preterm labor. In my view, this is not a reasonable answer; therefore, the other answers (which were derived by the same methods) must be viewed with circumspection.

If incidence of preterm labor among black women in the United States were used to calculate predictive values, the numbers would appear as in Table I.

These numbers are more reasonable and, on the basis of the findings of the study, are more "computationally" correct. Not surprisingly, the positive predictive values have decreased and the negative predictive values have increased.

Table I. Predictive values of certain signs and symptoms in a population with a 7% incidence of preterm labor

Sign or symptom	*Positive predictive value*	*Negative predictive value*
Contractions	0.52	0.98
Menstrual cramps	0.39	0.96
Intestinal cramps	0.39	0.94
Constant backache	0.65	0.95
Constant pelvic pressure	0.33	0.94
Vaginal discharge, amount	0.30	0.96
Vaginal discharge, color	0.39	0.95
Urinary frequency	0.32	0.94

The findings, however, must still be questioned because of the retrospective design of the study. The extrapolation of data derived from sampling a small portion of that population to the population as a whole is valid only if the selection of the sample population and the collection of data are done without bias. The authors concede that, "... a potentially significant limitation of retrospective questioning as done in this study cannot be ignored." This limitation is called "recall" or "ascertainment" bias and occurs because patients who are hospitalized for preterm labor are more likely to remember antecedent symptoms when the symptoms are associated with a pregnancy complication than are patients without a pregnancy complication who are being questioned in an outpatient setting.

The authors predict candidly, however, that a decline in sensitivity would occur if they relied on prospective, patient-initiated reporting because, "... pregnant women are more likely to be distracted in the out-of-hospital environment." They apparently make this point to emphasize the importance of educational prevention programs, but even an independent reviewer could not have made a statement more damaging to the credibility of this study.

I would petition Drs. Creasy and Katz to continue their superb educational efforts and to refine their meritorious surveillance techniques so that in the near future they may provide us with clinically applicable conclusions that are derived from data that have been obtained in an unbiased, prospective manner.

Reply

To the Editors: We thank Dr. Strickland for his excellent and insightful critique. Although we agree with many of the comments, we would like to point out a few issues that could help clarify the conclusions in our recent report (Katz M, Goodyear K, Creasy RK. Early signs and symptoms of preterm labor. AM J OBSTET GYNECOL 1990;162:1150-3.). Our Table V indeed gives the values that were computed in a population, which by our choice, had a 50% incidence of preterm labor. These facts are clearly given in our Material and methods section and can therefore hardly be considered to "contain a deceptive probability error." Once it is clear that the data in Table V are relevant for those high-risk populations whose incidence of preterm labor is

50% (multifetal gestations, multiple previous spontaneous preterm births, etc.), the calculations of predictive values are not only valid and reasonable but also "computationally" correct. Needless to say, because of the direct relationship between the incidence of an event and predictive values, a lower incidence of preterm labor will result in lower positive predictive values. This is very eloquently demonstrated in Dr. Strickland's computations for a 7% incidence of preterm labor. Nevertheless, even these "lower" positive predictive values, which range from close to 40% and up to 65% for signs or symptoms such as cramps, change in vaginal discharge, or constant backache, are very impressive and could serve quite well for the *purpose of screening* as to the possibility of preterm labor.

It should be emphasized that we did not, and still do not, propose use of these signs and symptoms to establish the diagnosis of preterm labor, but rather to screen patients' complaints. It is of note that a recent study by Iams et al.[1] confirmed the importance of these signs and symptoms in helping to screen patients who are at increased risk of preterm labor. More recently, Martin et al.[2] reported that among their patients who had preterm labor, subjective symptoms were the sole reason for evaluation in almost one quarter of the patients. Again, as stated in our article, all of the above-mentioned data cannot replace the need for a prospective unbiased study. It is indeed unfortunate that in spite of the fact that preterm delivery is the greatest contributor to perinatal mortality from any complication of pregnancy, that not one word was published on the early signs and symptoms of preterm labor when this study was begun. We eagerly invite others, and Dr. Strickland, to contribute their knowledge on the early signs and symptoms of preterm labor, which is the most significant hurdle to overcome in the achievement of a satisfactory reproductive outcome. However, until such additional data are available, use of such signs and symptoms for screening of reports that are made by high-risk patients, seems prudent.

Dr. Strickland's comments about the retrospective nature of our study and the issues of our subjects' recall bias were extensively stressed previously in our Comment section. We raise these issues not only to point out a potential role for educational prevention programs but also to discuss the potential weaknesses of our study. We thus accept Dr. Strickland's comments about us being our own severest critics with deep appreciation.

Successful treatment of postpartum shock caused by amniotic fluid embolism with cardiopulmonary bypass and pulmonary artery thromboembolectomy

To the Editors: Esposito et al. (Esposito RA, Grossi EA, Coppa G, et al. Successful treatment of postpartum shock caused by amniotic fluid embolism and pulmonary artery thrombolectomy. AM J OBSTET GYNECOL 1990;163:572-4.) are the first to describe thromboembolic elements in the pulmonary arteries in a case of amniotic fluid embolism, but they did not understand the pathogenetic significance of their observation.

It has been shown by Stolte (1971),[1] Lim (1972),[2] and Courtney and Allington (1972)[3] that amniotic fluid has clot-promoting activity. Amniotic fluid is not in need of proconvertin,[2] for it contains a proconvertin-like substance, and in high dilutions it is cephalin dependent.[4]

Animal experiments of Stolte et al.[5] and Lim[6] showed that the effects of amniotic fluid infusions were distinct from the clinical picture of amniotic fluid embolism. Such infusions give rise to a state of hypercoagulability: In the *circulating* blood 1 minute after injection, there was a shortening of the intact and activated clotting time, without a change in the level of factor I and the number of platelets[2] and with a simultaneous increase of factor V activity.[4] In *stagnant* blood, amniotic fluid infusion led to the formation of a clot.[1, 4, 7] Stasis of blood in the inferior vena cava after amniotic fluid infusion led to the formation of a clot, which, once the flow of blood was restored, was displaced to the pulmonary vessels.[4]

Only extremely large amounts of amniotic fluid caused diffuse intravascular clotting.[4] In an analysis of the mode of death in 96 cases of fatal amniotic fluid embolism from the literature, Kool[4] discerned the cases in which cardiovascular, respiratory, and cerebral accidents were responsible for the death from those in which bleeding that resulted from diffuse intravascular clotting led to maternal death. In the latter group rupture of the uterus was significantly more frequent.

From the investigations of Kerr (1964),[8] we know that in pregnant women in the second trimester of pregnancy, there is stasis of blood in the inferior vena cava when they are in the supine position. From this and in the light of the above-mentioned experiments, we believe that after laceration of the uterine blood vessels, amniotic fluid that reaches stagnant pools of blood in the large veins causes formation of clots, which later, when the flow of blood has been restored after delivery, reaches the lungs and causes the cardiorespiratory accident. When the amniotic fluid reaches the maternal circulation via a traumatic area (e.g., a rupture of the uterus) in which large amounts of thromboplastin are available, the amniotic fluid acts as a vehicle of this thromboplastin and causes diffuse intravascular clotting and a fatal loss of blood.

Intradecidual T lymphocytes lack T-cell receptors

To the Editors: We read with great interest the article by King and Loke (King A, Loke AW. Uterine large granular lymphocytes: A possible role in embryonic implantation? AM J OBSTET GYNECOL 1990;162:308-10) and would like to make some additional remarks on this subject.

In a recent report[1] we described the lack of expression of the two variants of the T-cell antigen receptor by mature T lymphocytes in first-trimester decidua that was obtained from women who were undergoing therapeutic abortions. Immunohistochemical analysis revealed considerable numbers of $CD3^+$ cells in the decidua, but antibodies against the structural components of the T-cell antigen receptor stained only very few (α/β–chain) or no (γ/δ–chain) cells. Thus the phenotype of these mature T cells can be described as follows: $CD3^+$, $\alpha/\beta-$, $\gamma/\delta-$. Normal percentages of $\alpha/\beta+$ T cells, however, could be demonstrated in the peripheral blood of these women. After in vitro culture for 3 weeks with phytohemagglutinin-H and recombinant interleukin-2, intradecidual T cells expressed the T-cell antigen receptor. Fluorescence-activated cell sorter analysis revealed $CD3^+$, $\alpha/\beta+$, and $\gamma/\delta-$ T cells. Our data clearly show that mature T cells, which constitute only a minority of the intradecidual leukocytes, do not express immunohistochemically detectable amounts of T-cell antigen receptor during early normal pregnancy. Since it is known that CD3 is not usually expressed on the cell surface without coexpression of the α/β or γ/δ heterodimer,[2] one explanation for our results could be that the density of T-cell antigen receptor proteins is below the threshold for detection with the antibodies that were applied (αF1, βF1, BMA031, WT31, TCR δ_1, δTCS1). This could be due to partial or complete internalization of the T-cell antigen receptor/CD3 complex. It is also possible that a conformational change has rendered the receptor molecule undetectable by the anti–T-cell antigen receptor antibodies. Either of these mechanisms could interfere with T-cell antigen recognition, since high-affinity binding cannot occur under such circumstances. As a consequence, there would be a state of anergy toward fetal antigens. This is probably one of the decisive mechanisms that is involved in local tolerance of the maternal immune system to the embryo.

Intraumbilical injection of oxytocin

To the Editors: I read with interest the recent correspondence by Golan (Golan A. Volume and timing are key to use of intraumbilical oxytocin for management of retained placenta. AM J OBSTET GYNECOL 1990;162: 1628-9). Dr. Golan first stated that the *routine* use of intraumbilical oxytocin shortens the third stage of labor. Subsequently, he stated that one should not inject the oxytocin until 30 minutes after delivery. Indeed, he criticized us[1] for injecting the oxytocin too soon (i.e., 5 minutes) after delivery. I am confused. If one is going to use this technique on a routine basis (a practice that I do not recommend), how can one wait until 30 minutes after delivery?

David H. Chestnut, MD

Departments of Anesthesia and Obstetrics and Gynecology, University of Iowa College of Medicine, Iowa City, IA 52242

REFERENCE

1. Chestnut DH, Wilcox LL. Influence of umbilical vein administration of oxytocin on the third stage of labor: a randomized, double-blind placebo-controlled study. AM J OBSTET GYNECOL 1987;157:160-2.

Reply

To the Editors: I appreciate Dr. Chestnut's comment but regret, however, that I was misunderstood. Neri et al.[1] and, recently, Reddy and Carey[2] have demonstrated the usefulness of the routine use of oxytocin in the management of the third stage of labor. The latter have shown in a randomized, controlled manner that such an application shortens the duration of the third stage and consequently diminishes blood loss.

The unnecessary confusion arises from the lack of differentiation between the *management of the third stage of labor* and the *management of the retained placenta.* I have consistently referred to the latter practice, and in spite of my appreciation of the findings and the clearly presented point by Reddy and Carey,[2] this was never our practice and I have never recommended such routine use of oxytocin for the management of the third stage of labor.

Intraumbilical injection of oxytocin seems to be an effective, quick, and safe method for the separation and delivery of the *retained placenta.* We recommend a waiting period of 30 minutes.[3]

Rh immune globulin prophylaxis for threatened abortions

To the Editors: I read with interest the article by Dayton et al. (Dayton VD, Anderson DS, Crosson JT, Cruikshank SH. A case of Rh isoimmunization: should threatened first-trimester abortion be an indication for Rh immune globulin prophylaxis? AM J OBSTET GYNECOL 1990;163:63-64). In this report, a patient with an Rh negative blood type with a first-trimester threatened abortion became isoimmunized to the D antigen later in her pregnancy. The authors make the assumption that the threatened abortion was the cause of the subsequent sensitization.

However, an antibody screen, which was performed 2 weeks after her presentation to the emergency room because of cramping and bleeding, was negative. At the time of a genetic amniocentesis at 15 weeks' gestation, the antibody screen was still negative, and the patient was given 300 μg of Rh immune globulin prophylactically. The next antibody screen at 29 weeks' gestation was positive, the cord blood antiglobulin test was strongly positive, and the patient's antibody screen remained positive even 6 months post partum. The authors make the assumption that the cause of the isoimmunization was the minor first-trimester hemorrhage.

The frequency of transplacental hemorrhage that occurs with threatened abortions is unknown. The use of Rh immune globulin for treatment of threatened abortions is thus not clearly defined. However, several alternative explanations for the patient's isoimmunization exist. First, a large transplacental hemorrhage may have occurred during the amniocentesis, and the standard dose of Rh immune globulin therefore may have been inadequate. The details of the amniocentesis are not described; we do not know the number of attempts at needle placement or whether the needle was directed through an anterior placenta.

Second, the presence of fetal red blood cells in the maternal circulation increases throughout gestation. Cohen et al.[1] and Clayton et al.[2] have shown, with the use of the Kleihauer-Betke test, that significant numbers of patients had fetal red blood cells in the maternal circulation, especially in the second and third trimesters. This significant degree of clinically silent transplacental hemorrhage may help explain the small percentage of women who become isoimmunized before the twenty-eight-week Rh immune globulin injection. A silent transplacental hemorrhage may well have occurred in this patient.

In summary, although the authors raise an important question, "Should Rh immune globulin be administered to Rh negative women with threatened abortions?," they do not sufficiently prove that a relationship existed in their patient between the bleeding that occurred during the first-trimester and the subsequent isoimmunization. What is needed is a study that compares the incidence of transplacental hemorrhage in women who present with threatened abortions versus a first-trimester control population. This study is currently ongoing.

Jeffrey A. Kuller, MD

Department of Obstetrics, Gynecology, and Reproductive Sciences, Reproductive Genetics Unit, University of California, San Francisco, San Francisco, CA 94143-0720.

REFERENCES

Reply

To the Editors: Thank you for forwarding Dr. Kuller's letter to us. His questions allow us to emphasize some very important points that, because of space limitations, we could not more fully illustrate in our report.

First, how could one be sure that the standard 300 μg vial of Rh immune globulin was sufficient to cover any bleeding from the amniocentesis at 15 weeks' gestation? Precise measurement of the volume of the fetoplacental circulation for all times during pregnancy is not available; however, the fetoplacental blood volume at term is approximately 125 ml/kg of fetal weight.[1] According to published tables, at 16 weeks' gestation a fetus weighs approximately 105 gm,[2] and therefore would have a whole blood volume (fetus and placenta) of approximately 13 ml. The standard vial of Rh immune globulin is sufficient to cover an exposure to 30 ml of Rh_o(D)-positive blood.[3] We made the assumption that this would be enough to cover even a lethal transplacental hemorrhage at 15 weeks' gestation

unless there was a product failure of the Rh immune globulin. To the best of our knowledge, there have been no reported failures of the product and lot number that our patient received.

Next, why was the antibody screen for our patient negative at 10 weeks' and at 15 weeks' gestation if the patient presumably was sensitized from a bleeding episode at 8.5 weeks' gestation? This is an extremely important point for clinical obstetricians. First, it requires several weeks for a primary response to a blood-group antibody to be detectable.[3] Second, we reported that the 15-week antibody screen for our patient was only performed with low ionic strength saline solution and without any enzyme enhancement. The anti-D antibody frequently requires enzyme enhancement to be detected if it is weak or developing[3] (as it would be at 15 weeks' gestation in our patient). For this reason, many laboratories routinely use enzyme enhancement for all obstetric antibody screening. We are confident that lack of enzyme enhancement was the reason that the seroconversion was not detected at 15 weeks' gestation in our patient.

As to whether or not this patient could have been sensitized as a result of small transplacental hemorrhages between the fifteenth and twenty-eighth gestational weeks, we again contend that the full dose of Rh immune globulin was more than ample to cover any bleeding from the amniocentesis at 15 weeks' gestation, and sufficient Rh immune globulin should have been present to cover any minor bleeding episodes between that time and 28 weeks' gestation.

Again, we thank you for giving us this opportunity to clarify these important points. We would also again like to question why it is that the American College of Obstetrics and Gynecology recommends the routine use of Rh immune globulin after chorionic villus sampling in the first trimester but not for spontaneous transplacental bleeding during the same time period.[4] Until a study such as the one Dr. Kuller mentions indicates otherwise, we will continue to recommend that our physicians give Rh immune globulin to women with the Rh_o(D)-negative blood type who have first-trimester bleeding whether or not they go on to abort spontaneously.

Koch's postulates: Revisited or revised?

To the Editors: During my years as an obstetrician-gynecologist, I have come to view the GRAY JOURNAL as the preeminent publication in our specialty. I have believed that the JOURNAL has set the standard for publications in our specialty. I am sure that our colleagues throughout the world agree.

It is therefore with a sense of dismay that I write this letter to you regarding a recently published article [Wiggins DA, Elliott JP. Oligohydramnios in each sac of a triplet gestation caused by Motrin—Fulfilling *Koch's postulates* (italics added). AM J OBSTET GYNECOL 1990;162:460-1].

It is, perhaps, that as I grow older my natural tendencies as a gadfly become more pronounced or, perhaps, my sense of purism is disturbed by historic inaccuracies, to wit: In 1882, Robert *Koch,* a Nobel Laureate in 1905, formalized the criteria that established the pathogenic character of a microorganism from that of an adventitious microbe. This statement became known as "Koch's postulates" (Koch R. Berl Klin Wochenschr 1882;19:221-30). These formalized criteria, which were introduced by Henle in 1840, state: (1) The organism is regularly found in lesions of the disease; (2) it can be isolated in pure culture on artificial media; (3) inoculation of this culture produces a similar disease in experimental animals; (4) the organism can be recovered from the lesions in these animals.

How the above could be unappreciated by the authors (who did not even present a reference to these "postulates") and how this could be overlooked and accepted by the Editors of the JOURNAL without comment is startling. Indeed, repeatedly the name *Koch* is misspelled as *Kock.*

I do not take offense with the fact that the authors wish to establish an appropriate deductive path to establish their case for the relationship of Motrin to oligohydramnios. However, it would have been preferable for them to use some approach other than the application of a set of principles that relates to microbial pathogenicity.

This editorial oversight is upsetting!

Thank you for patience in reviewing this matter.

Frontothalamic measurement in the second trimester of pregnancy

To the Editors: After we read the report of Goldstein, which was published in the JOURNAL in 1988 (Goldstein I, Reece EA, Pilu G, O'Connor TZ, Lockwood CJ, Hobbins JC. Sonographic assessment of the frontal lobe: A potential tool for prenatal diagnosis of microcephaly. AM J OBSTET GYNECOL 1988;158:1057-62) and which detailed a new fetal brain measurement, the

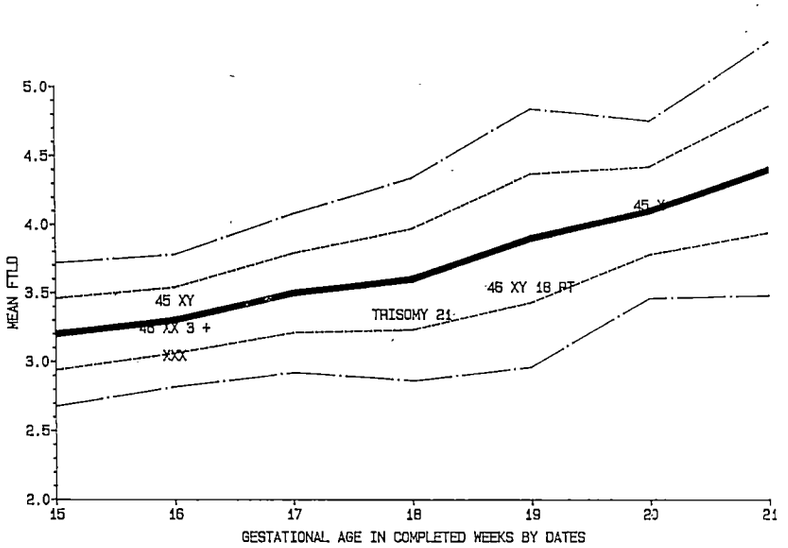

Fig. 1. Frontal thalamic lobe diameter (*FTLD* = 0.865 + BPD × 69.9) as determined by ultrasonography according to gestional age by dates. BPD is biparietal diameter. *FTLD* values are: ▬▬▬, mean; ————, +1 SD; —●—●—●—, ±2 SD.

"frontothalamic distance," we undertook a prospective study to determine whether there was any benefit in incorporating this measurement into routine second-trimester obstetric scanning. Our hope was that chromosomally abnormal fetuses could be distinguished by subtle changes that are due to a tendency toward microcephaly. Three hundred forty-two patients who were scheduled for amniocentesis were prospectively studied. Within this group, six abnormal chromosome analyses were found and plotted against the normal range that was found in our sample population. None of the chromosomally abnormal fetuses (trisomy 21, 46,XY; 45,X; 45,XY; XXX; 46,XX3+) fell outside of 1 SD of our prospective sample (Fig. 1).

In addition, a retrospective review of images that were previously obtained for seven trisomy 21 gestations were matched in a control group of 37 normal ultrasonographic studies. There was no significant difference in the frontothalamic lobe measurements for the trisomy group. Our evaluation suggests that, in spite of the authors' findings of its potential use in the prenatal diagnosis of microcephaly, this particular measurement does not appear to aid in the early diagnosis of chromosomally abnormal fetuses.

Prevalence of acquired immunodeficiency syndrome detected during prenatal care of population of low socioeconomic status

To the Editors: With reference to the article "Prevalence of human immunodeficiency virus in a general prenatal population" (Barton et al. AM J OBSTET GYNECOL 1989;160:1316-24) we would like to transmit the experience of the Faculdade de Ciências Médicas de Santos of São Paulo, Brazil. During 1988, we interviewed 803 pregnant women from our prenatal program. Of these, 514 agreed to undergo tests for the detection of anti-human immunodeficiency virus antibodies. We found 27 cases (5.2%) of positive enzyme-linked immunosorbent assay tests of which 19 cases (3.75%) were further confirmed by the synthetic peptide LGIWGCSKLIC test with the use of the gp 41 fraction. Our criteria to characterize the risk factors (Table I) differed from those established by Dr. Barton, probably because of socioeconomic factors and populational habits. We verified that of the 803 pregnant women who

Table I. Risk factors for AIDS to pregnant women

Two or more partners per month
Anal intercourse
Use of intravenous drugs
Sexual intercourse with intravenous drug addicts
Blood transfusions in the last 7 years
Partner with positive ELISA
Initiation of sexual life before the age of 15

ELISA, Enzyme-linked immunosorbent assay.

Table II. Distribution of the 803 pregnant women according to the risk rate for AIDS

Risk rate	*Factors*	*No.*	*%*
Low	0	447	55.6
Medium	1	212	26.4
High	≥2	144	18.0

were interviewed, 26.4% had one risk factor and 18% had two or more risk factors (Table II). Therefore 44.4% of our pregnant women have at least one risk factor for acquired immunodeficiency syndrome (AIDS). The positivity of anti-human immunodeficiency virus in women with no risk factor was 0.3%; in those with one risk factor it rose to 3.6%, and in the group with two or more risk factors it reached 14.1%.

The city of Santos has one of the world's highest prevalence rates for AIDS (61 cases per 100,000 inhabitants). Of the 520 cases that were registered before March 1990, 35% occurred in the female population. Therefore in this city, out of every 2000 women, one has AIDS. These results show the danger of heterosexual transmission and predict the high number of cases of AIDS that we will face in the near future.

Antonio Guilherme Moreira Porto, PhD
Department of Obstetrics, Faculdade de Ciencias Medicas de Santos, Rua Oswaldo Cruz 179, CEP 11.100-Santos, Sao Paulo, Brazil

Reply

To the Editors: I applaud Dr. Antonio Guilherme Moreira Porto's work in São Paulo, Brazil, and find his observation of our work most interesting. Again, however, it points out the confusion we suffer from in comparing data when we are restricted in our ability to use verified, standardized epidemiologic techniques in investigation of this disease.

The following are a few comments concerning the methods and findings in our article versus Dr. Porto's.

We do not consider a single positive enzyme-linked immunosorbent assay to be significant. A repeat procedure is ordered and only if *both* are positive do we submit specimens for more definitive Western blot studies.

The incidence of one of every 2000 women with acquired immunodeficiency syndrome in São Paulo is truly startling. I can only assume there is a high incidence of prostitution and/or intravenous drug use in this community.

It is interesting that the distribution of risk factors by percent (>37%) is much higher than ours. Indeed our principal risk factors are even different.

I submit a brief summary of the Chicago experience with acquired immunodeficiency syndrome to date for the Editors and authors to consider in comparing the Chicago experience with the São Paulo experience.

Since our study was first presented, we have now tested >1600 pregnant women in our clinics and the statistical outcomes have not significantly altered. By far (80%), the infections in our female population have been related to substance abuse by either patient or partner(s). This remains the highest risk factor in our study population.

John J. Barton, MD
Department of Obstetrics and Gynecology, Illinois Masonic Medical Center, 836 West Wellington Ave., Chicago, IL 60657

A chill wind blows fresh air

To the Editors: The Clinical Opinion article by Chavkin and Rosenfield in the August 1990 issue (Chavkin W, Rosenfield A. A chill wind blows: Webster, obstetrics, and the health of women. Am J Obstet Gynecol 1990;163:450-2) demonstrates the seriousness of the threat to abortion on demand that has been posed by recent events. The threat has now mobilized abortion rights supporters to action, which now apparently includes exercising the constitutional right to hyperbole. Chavkin and Rosenfield's arguments include raising the specter of thousands of dead women and a police state with listening devices in examination rooms. In addition, they seem to believe that abortion is a reasonable solution to most adverse perinatal and maternal health outcomes. Their conclusion is presumptuous at best when they imply that truly dedicated obstetricians will work vigorously to ensure that unrestricted abortion is part of reproductive health care.

In maternal-fetal medicine practice I care for two patients in the mother and the unborn child, and I rarely find a medical need to interfere with the continued existence of the fetus. The majority of abortion opponents have no argument with abortion for medical indications. But the recently proposed restrictions on abortion are meant to prohibit the 95% of procedures that are done for nonmedical reasons.

In the last decade I have seen too many physicians who have been intimidated into silence by vocal spokespersons for abortion on demand. Now they demand our unconditional support as they suffer reverses in the ongoing battle in the courts and legislatures. The authors of this Clinical Opinion, as well as many others in our profession, are unwilling to give an inch in their support of abortion on demand. In spite of their intransigence, they should not be surprised to find that, as the tide turns, the right to privacy will not include the unrestricted right to abort a fetus.

Steve Calvin, MD
5806 Oakland Ave. S., Minneapolis, MN 55417

Webster should not affect prenatal diagnosis

To the Editors: We note with some concern remarks made by Chavkin and Rosenfield in their recent article (Chavkin W, Rosenfield A. A chill wind blows: Webster, obstetrics, and the health of women. Am J Obstet Gynecol 1990;163:450-2). They state, "Implicit in offering α-fetoprotein screening, chorionic villus sampling, amniocentesis for karyotyping, and other probes for specific fetal abnormalities is the option of termination of pregnancy. Without such an option, there is little rationale for carrying out these testing procedures." Although we have no argument with a careful reading of the first sentence, we do disagree with the second sentence. With this statement, Chavkin and Rosenfield are not considering the value of prenatal diagnostic information for the management of labor and delivery, anticipation of the need for (or futility of) neonatal care, or the increasing possibilities for in utero treatment of the abnormal fetus. Nor are they considering that in cases in which fetal death is a possibility, current prenatal diagnostic techniques may be the last op-

portunity to make accurate diagnoses so that the parents can make informed decisions about future reproduction.

Like Chavkin and Rosenfield, we are eager to offer women a full range of reproductive options, but we think that the issues should not be clouded by such ill-considered statements as the second sentence cited above. A considerable number of our patients do opt, for a variety of reasons, to continue their pregnancies with the knowledge that the fetus is not normal. We offer these women our full support of their decision, just as we offer our full support if they decide that termination is the best choice for them.

Chavkin and Rosenfield also express their concern that the Webster decision may lead to limitations of the obstetrician's ability to "counsel patients about the option or *advisability* of termination of pregnancy" [emphasis added]. We take issue with any obstetrician who advises a woman to have an abortion solely because her fetus is abnormal, and a number of our patients have reported that this is what has happened to them. Certainly a case can be made for advising termination of pregnancy when the pregnancy has an adverse effect on the mother's health. For fetal abnormality, abortion should be presented as one option in the context of all available options.

Mason Barr, Jr., MD, Robert H. Hayashi, MD, H. Frank Andersen, MD, Gabriella C. Pridjian, MD, and Clark E. Nugent, MD

Division of Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, The University of Michigan, Ann Arbor, MI 48109

Reply

To the Editors: Dr. Calvin has written a generally critical letter concerning our recent article on abortion and the Supreme Court's Webster decision. He chastises us for raising the "specter of thousands of dead women." Perhaps he is unaware that illegal abortion is estimated by the World Health Organization to account for between 20% and 40% of the approximately 500,000 pregnancy-related deaths that are estimated to occur each year in the developing world. Furthermore, he must not know the data from the United States, which demonstrated a dramatic decline in death from illegal abortion after the legalization of abortion in the early 1970s.

He also misses our point when he states that medically indicated abortions are rare. It is the *purpose* of prenatal diagnosis that is threatened by these restrictions on abortion, even if relatively few procedures result in a positive diagnosis. Screening tests that are applied to populations will, of course, detect far fewer cases than people who are screened. Such screening tests are useful because of the possibility of subsequent action if they prove positive, which in this case would include the option of termination of the pregnancy.

Dr. Barr and colleagues express concern that we presume abortion to be the sole course of action after an abnormal prenatal diagnosis. This is not the case; we concur with them that such a diagnosis can be useful to medical management and future planning and that such decisions must be the patient's. Furthermore, we agree that, in counseling patients, the appropriate approach is to discuss options and not to suggest what is advisable. However, we also believe that the efficacy and availability of therapeutic possibilities for fetal abnormalities remains limited at the present time. We maintain therefore that the option of abortion is essential for prenatal diagnostic efforts to be a meaningful component of standard prenatal care. Moreover, future explorations in prenatal diagnosis and other aspects of reproductive medicine will be severely constricted if the Webster prohibition against termination after fertilization is deemed enforceable.

Our basic point here, however, is a larger one, namely, that the kinds of governmental restrictions that are exemplified by the Webster decision are not medically sound nor are they appropriate for governmental control. They place restrictions on the long-standing confidential relationship between a physician and his or her patient and interfere with the scientific basis on which the practice of medicine is based.

Furthermore, the impact of the Webster decision will be to aggravate disparities in health status and access to care as it is related to income. By effectively imposing delay on poor women who seek abortions, the State of Missouri imposes health risks on the very group that is already at highest risk.

Our article did not address abortion as an abstract or moral issue, a matter on which we and Dr. Calvin clearly disagree. Rather, our effort was to attempt to delineate for obstetrician-gynecologists some of the ways in which Webster-style restrictions on abortion will undermine the autonomy and integrity of our profession.

Wendy Chavkin, MD, MPH, and Allan Rosenfield, MD

Columbia School of Public Health and the Department of Obstetrics and Gynecology, Columbia Presbyterian Medical Center, 600 West 168th St., New York, NY 10032

Correction

In the article by Manabe and Yoshida, "Morphologic study of changes of collagenous tissue in the amnion and cervix during prostaglandin-induced abortion and delivery" (AM J OBSTET GYNECOL 1990;163:52-6), Fig. 1 on page 53 was printed upside down. As a result, the legend was incorrect; the figure information was correct from bottom to top rather than from top to bottom.

HIGH-RISK OBSTETRICS

The Saudi Arabian Oil Company's (SAUDI ARAMCO) Medical Services Organization in Saudi Arabia is interviewing for experienced Obstetricians/Gynecologists with subspecialty in maternal fetal medicine to join an Obstetrical staff of 16.

With a patient population of approximately 200,000, Saudi Aramco's medical facilities provide comprehensive medical care to our employees and their dependents. The Dhahran Health Center, recently expanded to 483-beds, offers all major specialty services as well as sub-specialties and functions as a referral center. American Board Certification and two years' experience after residency required. Strong leadership qualities and experience in both a professional and administrative capacity are preferred.

As a Saudi Aramco employee, you will receive a competitive base compensation package, as well as an expatriate premium. Additional benefits include noncontributory group life insurance, company-matched savings, free medical care at Saudi Aramco's hospital and clinics, housing inside a company community, and extensive recreation facilities and activities. Your eligible children will be enrolled in company schools, comparable to U.S. private schools. There are up to 13 company holidays annually, and you will be eligible for 36 calendar days of vacation, with round trip airfares to the U.S. or Canada for you and your family.

Investigate these truly unique opportunities by calling **OUR 24 HOUR, 7 DAYS PER WEEK TOLL-FREE NUMBER LISTED BELOW.**

Baltimore Partnership

THERE'S NOTHING EXTRAORDINARY

About This Practice!

We're tired of seeing ads for the most incredible OB/GYN practices this side of Mars. This isn't one of them!

On the outskirts of Baltimore, these partners **don't** deliver 1000 babies a year, perform 15,000 office procedures or 5,000 surgeries. And they **don't** net millions per doctor.

But they have an intangible. Not only are these two board ceritified physicians a long established, most respected practice, but. . . . . **THEY LOVE THEIR PATIENTS AND THEIR PRACTICE!**

They're looking to add an associate who'll quickly become a partner. Interim salary and benefits are great, too.

Call today for all the details without obligation. You owe **nothing**! The practice pays all fees, expenses, etc. And we'll put you in direct contact with the physicians.

Contact Bill Gregory, MedQuest, Inc., P.O. BOX MQ, Devault, PA 19432-0160 or call 215/640-3774.

MedQuest INC.

NORTHERN CALIFORNIA

The Permanente Medical Group, a growing multispecialty group, is recruiting physicians in a variety of specialties for positions throughout our beautiful Northern California region: the San Francisco Bay Area, Sacramento and the Central Valley.

Obstetrician/Gynecologist

BC/BE Obstetrician/Gynecologist sought to join small congenial clinic setting within established pre-paid multispecialty group. Practice consists of general obstetrics and gynecology, high risk obstetrics and infertility. Expertise in colposcopy, laparoscopy, hysteroscopy and laser are welcomed. Association with resident staff and teaching opportunities available.

Kaiser Permanente offers competitive salaries and excellent benefits including full coverage malpractice insurance, medical, dental and group life insurance, vacation, educational leave and an excellent retirement program.

Good People. Good Medicine.

FACULTY POSITION MATERNAL/FETAL MEDICINE

The department of Obstetrics and Gynecology at the University of Tennessee College of Medicine is actively recruiting a full-time Perinatologist for its Division of Maternal/Fetal Medicine.

The teaching hospital serves as the Tertiary Care Center for 80 counties in West Tennessee, East Arkansas, North Mississippi, Southern Missouri and a part of Kentucky; an area with approximately 40,000 deliveries per year. About 50% of the pregnancies delivered at the center are high risk pregnancies. Perinatal services each year include over 20,000 outpatient visits, 7,800 deliveries and over 1,400 patients seen in Reproductive Genetics.

Excellent opportunity to participate in teaching in a Board-approved fellowship program and collaborate in ongoing research in clinical Perinatology, Critical Care in Obstetrics, Ultrasound and Prenatal Diagnosis.

COMPETITIVE SALARY, ATTRACTIVE BENEFITS PACKAGE AND PROTECTED RESEARCH TIME.

Board eligibility/certification in Maternal/Fetal Medicine is required. Interested candidates should send curriculum vitae to:

Baha M. Sibai, M.D.
Division of Maternal/Fetal Medicine
University of Tennessee, Memphis
853 Jefferson Avenue, Rm. E-102
Memphis, TN 38103
(901) 528-5660

The University of Tennessee, Memphis is an equal employment opportunity/affirmative action/Title IX/Section 504 employer

The one drug test a woman can't afford to fail.

Knowing the right answers to this test can mean the difference between life and death to a woman and her unborn child. Cut it out now and give copies to all your patients, even if you don't suspect a drug problem. Even if they are not pregnant. Because if your patients don't know the right answers, now's the time to talk with them and help them to understand.

Drugs and Pregnancy: Did you know?

1. Did you know that if you use cocaine while you're pregnant, you have a much greater chance of having a miscarriage? ☐ YES ☐ NO

2. Did you know that if you use cocaine, you can pass it on to your baby through your breast milk? ☐ YES ☐ NO

3. Did you know that if you use any illicit drug while you're pregnant, there's a greater chance that you will have a low-birthweight baby? ☐ YES ☐ NO

4. Did you know that low birthweight is associated with a greater risk of infant death and mental and physical handicaps? ☐ YES ☐ NO

5. Did you know that heroin use during pregnancy increases the likelihood of stillbirth and death among newborns? ☐ YES ☐ NO

6. Did you know that if you or any of your sexual partners ever used an illicit IV drug, you may be infected with the AIDS virus (HIV), and that you can pass that virus on to your unborn child? ☐ YES ☐ NO

7. Did you know that if you use cocaine, are addicted to heroin, or are methadone-dependent, your children will be at a greater risk for sudden infant death syndrome (SIDS)? ☐ YES ☐ NO

8. Did you know that if you use barbiturates during your pregnancy you can change your child's normal patterns of growth and behavior? Your child might also suffer withdrawal symptoms for months after birth, including high-pitched crying, irritability, and sleep disturbances. ☐ YES ☐ NO

9. Is your doctor aware of all the prescription and/or illicit drugs you may be taking? ☐ YES ☐ NO

Did you know that if you have a drug problem, there are many people and resources you can turn to for help? Just ask your doctor. ☐ YES ☐ NO

Cut along dotted line, copy, and distribute to patients as you see fit.

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Smooth Sailing!

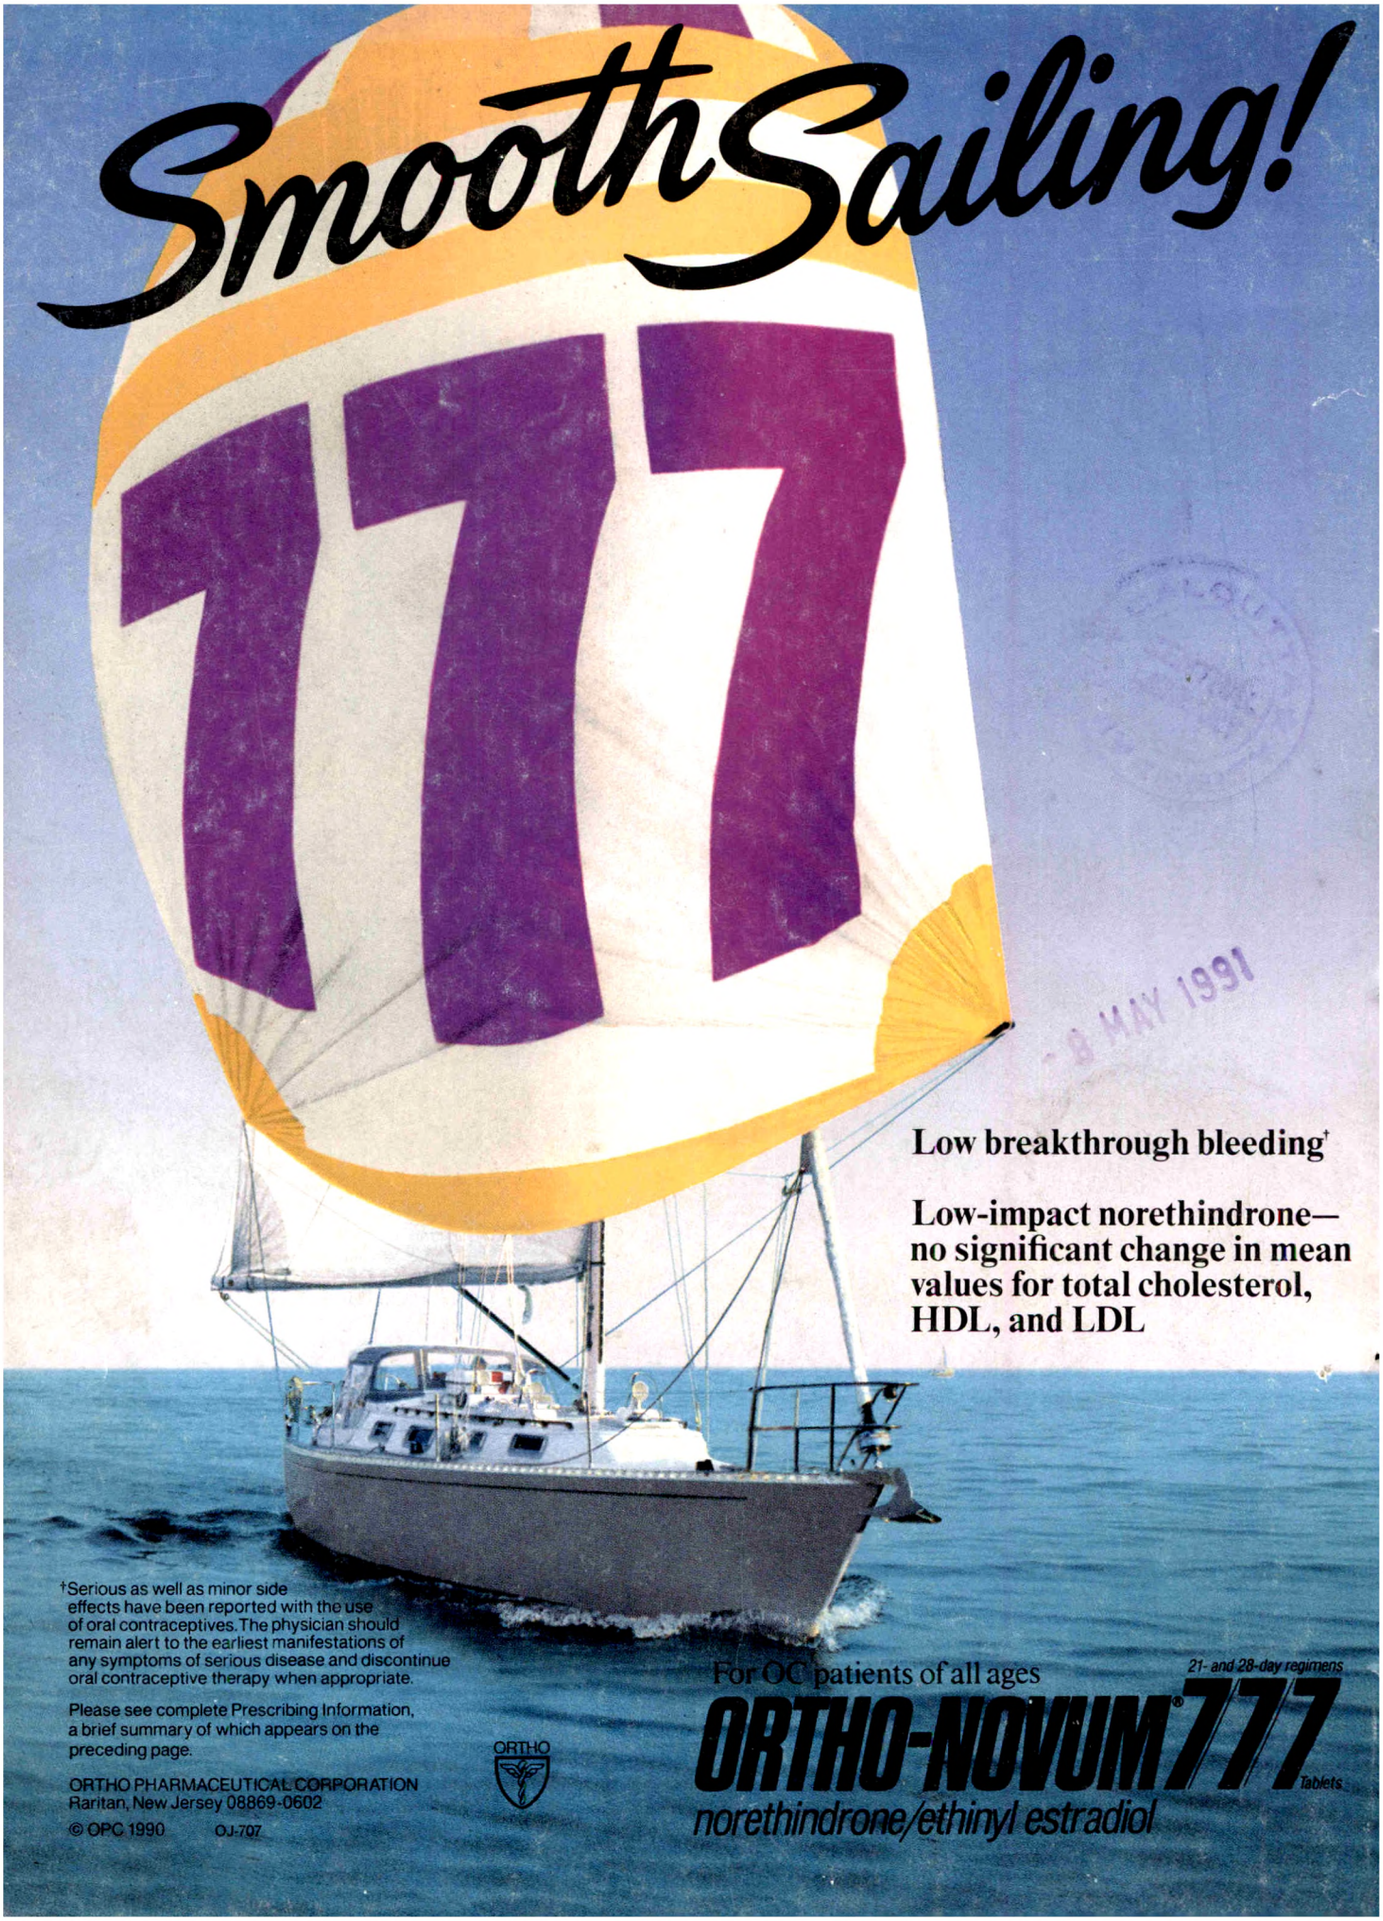
Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28 day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS



Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL®

Uniquely phased for all phases of a woman's reproductive life

ORAL CONTRACEPTIVE AGENTS: BRIEF SUMMARY

DESCRIPTION

TRI-NORINYL 21-DAY Tablets provide an oral contraceptive regimen of 7 blue tablets followed by 9 yellow-green tablets and 5 more blue tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg and each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg.

TRI-NORINYL 28-DAY Tablets provide a continuous oral contraceptive regimen of 7 blue tablets, 9 yellow-green tablets, 5 more blue tablets, and then 7 orange tablets. Each blue tablet contains norethindrone 0.5 mg and ethinyl estradiol 0.035 mg, each yellow-green tablet contains norethindrone 1 mg and ethinyl estradiol 0.035 mg, and each orange tablet contains inert ingredients.

INDICATIONS AND USAGE

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use these products as a method of contraception.

CONTRAINDICATIONS

Oral contraceptives should not be used in women who have the following conditions: Thrombophlebitis or thromboembolic disorders • A past history of deep vein thrombophlebitis or thromboembolic disorders • Cerebral vascular or coronary artery disease • Known or suspected carcinoma of the breast • Carcinoma of the endometrium, and known or suspected estrogen-dependent neoplasia • Undiagnosed abnormal genital bleeding • Cholestatic jaundice of pregnancy or jaundice with prior pill use • Hepatic adenomas, carcinomas or benign liver tumors • Known or suspected pregnancy

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia and gallbladder disease, although the risk of serious morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, hypercholesterolemia, obesity and diabetes.

Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with formulations containing 0.05 mg or higher of estrogen. The effects of long-term use with lower dose formulations of both estrogens and progestogens remain to be determined.

Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease. Relative risk, the *ratio* of the incidence of a disease among oral contraceptive users to that among non-users, cannot be assessed directly from case control studies, but the odds ratio obtained is a measure of relative risk. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide not only a measure of the relative risk but a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and non-users. The attributable risk does provide information about the actual occurrence of a disease in the population.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS

a. Myocardial infarction

An increased risk of myocardial infarction has been attributed to oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be 2 to 6. The risk is very low under the age of 30. However, there is the possibility of a risk of cardiovascular disease even in very young women who take oral contraceptives.

Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women 35 or older, with smoking accounting for the majority of excess cases.

Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives.

Oral contraceptives may compound the effects of well-known risk factors for coronary artery disease, such as hypertension, diabetes, hyperlipidemias, hypercholesterolemia, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and impair oral glucose tolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see **WARNINGS,** section 9). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. Thromboembolism

An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. One cohort study has shown the relative risk to be somewhat lower, about 3 for new cases (subjects with no past history of venous thrombosis or varicose veins) and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped.

A 2- to 6-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. If feasible, oral contraceptives should be discontinued at least 4 weeks prior to and for 2 weeks after elective surgery and during and following prolonged immobilization. Since the immediate postpartum period also is associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than 4 to 6 weeks after delivery in women who elect not to breast feed.

c. Cerebrovascular diseases

An increase in both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes) has been shown in users of oral contraceptives. In general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users for both types of strokes while smoking interacted to increase the risk for hemorrhagic strokes.

In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk also is greater in women 35 or older and among smokers.

d. Dose-related risk of vascular disease from oral contraceptives

A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with some progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogens used in the contraceptives. The amount of both hormones should be considered in the choice of an oral contraceptive.

Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing the lowest estrogen content that produces satisfactory results for the individual.

e. Persistence of risk of vascular disease

There are three studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for 5 or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. Subarachnoid hemorrhage also has a significantly increased relative risk after termination of use of oral contraceptives. However, these studies were performed with oral contraceptive formulations containing 0.05 mg or higher of estrogen.

2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE

One study gathered data from a variety of sources which have estimated the mortality rates associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral contraceptive users is based on data gathered in the 1970's—but not reported in the U.S. until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral contraceptive use to women who do not have the various risk factors listed in this labeling.

Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular disease risks may be increased with oral contraceptive use after age 40 in healthy non-smoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception.

Therefore, the Committee recommended that the benefits of oral contraceptive use by healthy non-smoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. CARCINOMA OF THE BREAST AND REPRODUCTIVE ORGANS

Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and non-users and differences in age at start of use, has been questioned. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use.

Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors.

In spite of many studies of the relationship between oral contraceptive use and breast or cervical cancers, a cause and effect relationship has not been established.

4. HEPATIC NEOPLASIA

Benign hepatic adenomas are associated with oral contraceptive use although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases per 100,000 for users, a risk that increases after 4 or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage.

Studies in the United States and Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are extremely rare in the United States and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users is less than 1 per 1,000,000 users.

5. OCULAR LESIONS

There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY

Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. More recent studies do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy.

The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion.

It is recommended that for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued if pregnancy is confirmed.

7. GALLBLADDER DISEASE

Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS

Oral contraceptives have been shown to impair oral glucose tolerance. Oral contraceptives containing greater than 0.075 mg of estrogen cause glucose intolerance with impaired insulin secretion, while lower doses of estrogen may produce less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives.

Some women may develop persistent hypertriglyceridemia while on the pill. As discussed earlier (see **WARNINGS**, sections 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users.

9. ELEVATED BLOOD PRESSURE

An increase in blood pressure has been reported in women taking oral contraceptives. The incidence of risk also was reported to increase with continued use and among older women. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing concentrations of progestogens.

Women with a history of hypertension or hypertension-related diseases or renal disease should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives and there is no difference in the occurrence of hypertension among ever- and never-users.

10. HEADACHE

The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. BLEEDING IRREGULARITIES

Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first 3 months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out.

Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was pre-existent.

PRECAUTIONS

1. PHYSICAL EXAMINATION AND FOLLOW-UP

A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care.

2. LIPID DISORDERS

Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult.

3. LIVER FUNCTION

If jaundice develops in any woman receiving oral contraceptives the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function.

4. FLUID RETENTION

Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention.

5. EMOTIONAL DISORDERS

Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree.

6. CONTACT LENSES

Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist.

7. DRUG INTERACTIONS

Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines.

8. INTERACTIONS WITH LABORATORY TESTS

Certain endocrine and liver function tests and blood components may be affected by oral contraceptives:

a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG. Free T4 concentration is unaltered.

c. Other binding proteins may be elevated in serum.

d. Sex steroid binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged.

e. Triglycerides may be increased.

f. Glucose tolerance may be decreased.

g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives.

9. CARCINOGENESIS

See **WARNINGS** section.

10. PREGNANCY

Pregnancy Category X. See **CONTRAINDICATIONS** and **WARNINGS** sections.

11. NURSING MOTHERS

Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

INFORMATION FOR THE PATIENT

See **PATIENT LABELING.**

ADVERSE REACTIONS

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see **WARNINGS** section): Thrombophlebitis • Arterial thromboembolism • Pulmonary embolism • Myocardial infarction • Cerebral hemorrhage • Cerebral thrombosis • Hypertension • Gallbladder disease • Hepatic adenomas, carcinomas or benign liver tumors

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis • Retinal thrombosis

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea • Vomiting • Gastrointestinal symptoms (such as abdominal cramps and bloating) • Breakthrough bleeding • Spotting • Change in menstrual flow • Amenorrhea • Temporary infertility after discontinuation of treatment • Edema • Melasma which may persist • Breast changes: tenderness, enlargement, secretion • Change in weight (increase or decrease) • Change in cervical erosion and secretion • Diminution in lactation when given immediately postpartum • Cholestatic jaundice • Migraine • Rash (allergic) • Mental depression • Reduced tolerance to carbohydrates • Vaginal candidiasis • Change in corneal curvature (steepening) • Intolerance to contact lenses

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome • Cataracts • Changes in appetite • Cystitis-like syndrome • Headache • Nervousness • Dizziness • Hirsutism • Loss of scalp hair • Erythema multiforme • Erythema nodosum • Hemorrhagic eruption • Vaginitis • Porphyria • Impaired renal function • Hemolytic uremic syndrome • Budd-Chiari syndrome • Acne • Changes in libido • Colitis

OVERDOSAGE

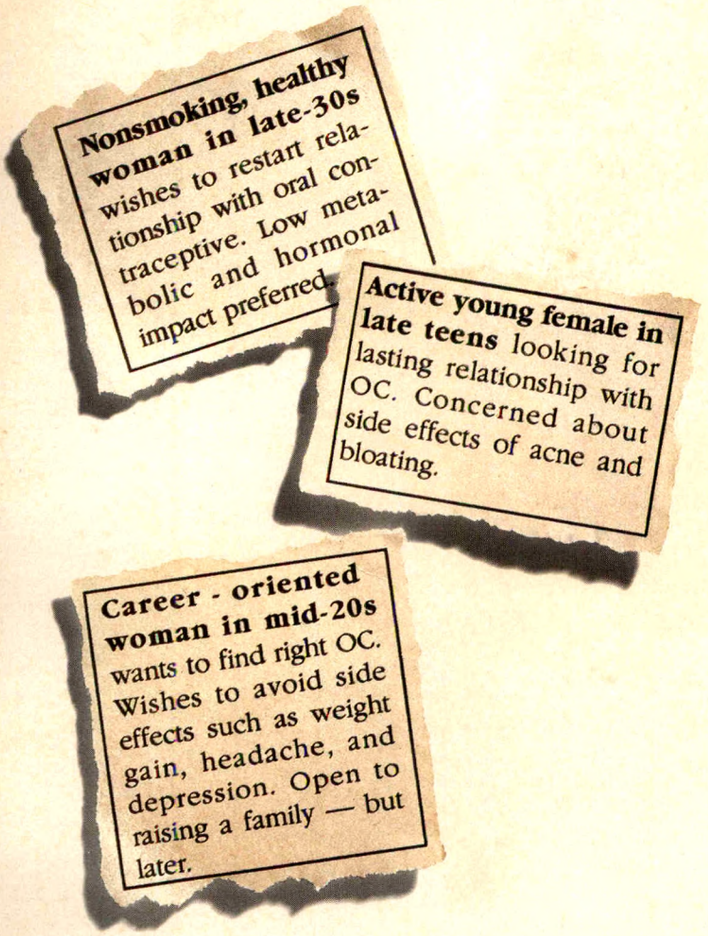
Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

NON-CONTRACEPTIVE HEALTH BENEFITS

The following non-contraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral contraceptive formulations containing estrogen doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: • Increased menstrual cycle regularity • Decreased blood loss and decreased incidence of iron deficiency anemia • Decreased incidence of dysmenorrhea

Effects related to inhibition of ovulation: • Decreased incidence of functional ovarian cysts • Decreased incidence of ectopic pregnancies



Effects from long-term use: • Decreased incidence of fibroadenomas and fibrocystic disease of the breast • Decreased incidence of acute pelvic inflammatory disease • Decreased incidence of endometrial cancer • Decreased incidence of ovarian cancer

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

A personalized approach to oral contraceptives.

Because Tri-Norinyl is uniquely phased for all phases of a woman's reproductive life, it's ideal for a wide range of patient types:

Older, nonsmoking patients restarting contraception: The only multiphasic with norethindrone that *lowers* progestin in late cycle to minimize overall hormonal and metabolic impact.

Career-oriented patients delaying childbearing: Reduced progestin helps minimize side effects such as weight gain, headache, and depression.

Younger patients just starting contraception: Low-impact progestin lowers risk of acne and bloating; mid-cycle increase enhances support when breakthrough bleeding is most likely to occur.

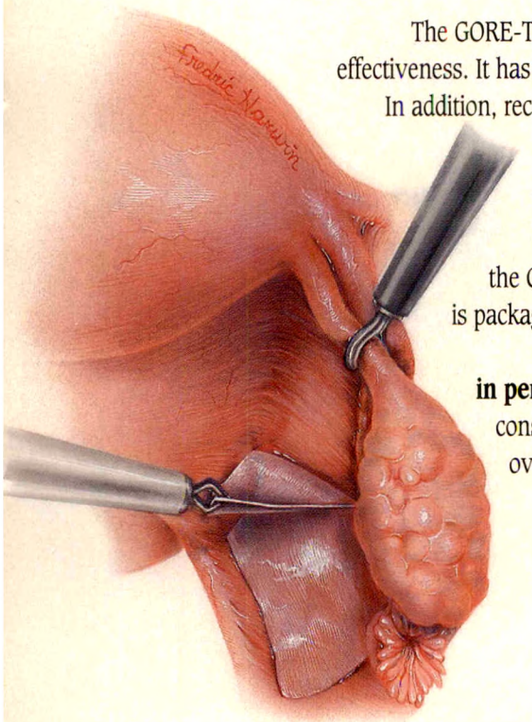
in Adhesions...

...The GORE-TEX® Surgical Membrane
The Choice in Peritoneal Reconstruction



Successful peritoneal reconstruction requires dependable measures to minimize adhesion reformation following adhesiolysis. The invariant performance of the GORE-TEX Surgical Membrane aids in producing consistent results.

Performance by Design

Composed of the inert biomaterial, expanded polytetrafluoroethylene (e-PTFE), the GORE-TEX Surgical Membrane limits tissue attachment with an extremely small pore size. The nonabsorbable material is a physical barrier which minimizes adhesion between adjacent tissues.

Proven and Established

The GORE-TEX Surgical Membrane has a long record of safety and effectiveness. It has demonstrated reliability among cardiac surgeons for more than 14 years. In addition, recent use in a multi-center clinical study has substantiated safety and shown invariant performance in peritoneal repair.

Convenient

Available in specific configurations tailored for pelvic adhesion reduction, the GORE-TEX Surgical Membrane – *Configured for Peritoneal Reconstruction* is packaged sterile and **can be resterilized**.

Choose the GORE-TEX Surgical Membrane for invariant performance in peritoneal reconstruction. To receive further information or to consult an application specialist, call **800-437-8181**. For orders and overnight delivery 24 hours a day, please call **800-528-8763**.

Corometrics puts the power of convex technology in your hand

The Aloka 620...
Outstanding image quality and more useful clinical information!

Practitioner tested and proven, convex array technology eliminates the problem of a narrow near field of view as seen with conventional sector scanners. A full wide aperture is maintained throughout the entire field of view, preserving resolution even at the sides of the sector scan.

Convex scan shows more clinical information.

A wide range of convex transducers is available, including our unique endovaginal probe designed for ease of use, unsurpassed control, and superior image quality. Advanced software includes an on-screen report page. The Aloka 620 — it all adds up to a new level of power and versatility for your office.

For more information or a demonstration call 1-800-624-7265, ext. 453 or 515.
In Connecticut call 265-5631.

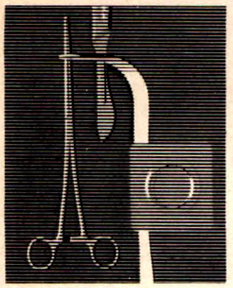
CEFOTAN® IM/IV


(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.
DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.
HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

Evaluation of an aneurysm of the vein of Galen in utero by pulsed and color Doppler ultrasonography 743
Junji Ishimatsu, MD, Osamu Yoshimura, MD, Masahiro Tetsuou, MD, and Teiji Hamada, MD
Fukuoka-Ken, Japan

A definitive diagnosis of an aneurysm of the vein of Galen in utero was made at 37 weeks of gestation with pulsed and color Doppler ultrasonography.

Epidermal growth factor receptor expression in normal ovarian epithelium and ovarian cancer. II. Relationship between receptor expression and response to epidermal growth factor 745
Gustavo C. Rodriguez, MD, Andrew Berchuck, MD, Regina S. Whitaker, BS, David Schlossman, MD, PhD, Daniel L. Clarke-Pearson, MD, and Robert C. Bast, Jr., MD
Durham, North Carolina

Loss of responsiveness to epidermal growth factor in ovarian cancer cell lines is not due to decreased receptor expression.

Prenatal diagnosis of myotonic muscular dystrophy with linked deoxyribonucleic acid probes 751
Aubrey Milunsky, MB, BCh, DSc, DCH, James C. Skare, PhD, Jeffrey M. Milunsky, BA, Thomas A. Maher, BS, and Jean A. Amos, PhD
Boston, Massachusetts

Prenatal diagnosis of myotonic muscular dystrophy, with the use of deoxyribonucleic acid probes, can now be provided with high degrees of certainty for almost all families.

Prevention of preterm birth in high-risk patients: The role of education and provider contact versus home uterine monitoring 756
Donald C. Dyson, MD, Yvonne M. Crites, MD, Deborah A. Ray, MD, and Mary Anne Armstrong, MA
Santa Clara and Oakland, California

Home uterine monitoring was found to be more effective than education alone in the prevention of preterm birth in twin gestations but not in singleton gestations.

Impact of tubal sterilization and vasectomy on female marital sexuality: Results of a controlled longitudinal study 763
Rochelle N. Shain, PhD, Warren B. Miller, MD, Alan E.C. Holden, MA, and Marc Rosenthal, MD, PhD
San Antonio, Texas, and Palo Alto, California

There are no detrimental short- or long-term effects and some short-term benefits of tubal sterilization and vasectomy on female marital sexuality.

The "Allis" test for easy cesarean delivery 772
Michael A. Finan, MD, Dimitrios S. Mastrogiannis, MD, PhD, and William N. Spellacy, MD
Tampa, Florida

A test is described that may reduce dystocia at cesarean delivery

Flow velocity waveforms of the fetal circulation preceding fetal death in a case of lupus anticoagulant 776
Giancarlo Mari, MD, and Nathan Wasserstrum, PhD, MD
Houston, Texas

Serial Doppler ultrasonography evidenced that the "brain-sparing effect" was transitory and disappeared before fetal death.

Recurrent herpes gestationis with postpartum flare: A case report 778
Laxmi V. Baxi, MD, Oormila P. Kovilam, MD, Margaret H. Collins, MD, and Robert R. Walther, MD
New York, New York

In this patient herpes gestationis occurred in five pregnancies, with postpartum onset of lesions in the last pregnancy, which also showed placental changes.

Transvaginal color Doppler imaging in the assessment of uteroplacental blood flow in the normal first-trimester pregnancy 781
Richard Jaffe, MD, and Steven L. Warsof, MD
Chicago, Illinois

Transvaginal color Doppler imaging was used to assess trophoblastic blood flow in early normal pregnancy; characteristic changes in diastolic blood flow were found as early as 5 weeks' gestation.

Small-for-gestational-age birth: Maternal predictors and comparison with risk factors of spontaneous preterm delivery in the same cohort 785
Barbara Abrams, DrPH, RD, and Vicky Newman, MS, RD
Berkeley, San Francisco, and San Diego, California

Different maternal risk factors were associated with small-for-gestational-age infants and preterm delivery in the same cohort.

Antisperm antibodies to sperm surface antigens in women with genital tract infection 791
Dean S. Cunningham, MD, PhD, David L. Fulgham, BS, David L. Rayl, MD, Keith A. Hansen, MD, and Nancy J. Alexander, PhD
Portsmouth and Norfolk, Virginia

Pelvic infections lead to the production of antisperm antibodies that differ in specificity from those generated by other causes, including lower genital tract infections.

Genotyping of macerated stillborn fetuses 797
Catherine Derom, PhD, Robert Vlietinck, MD, Robert Derom, MD, Charles Boklage, PhD, Michel Thiery, MD, and Herman Van den Berghe, MD
Leuven and Ghent, Belgium, and Greenville, North Carolina

The analysis of deoxyribonucleic acid extracted from the placenta allows for accurate genotyping of macerated stillborn fetuses.

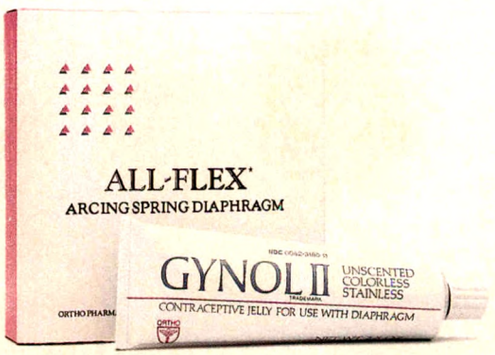
To be continued...

Continuation...an excellent indicator of patient satisfaction.

The Ortho ALL-FLEX* Arcing Spring Diaphragm



- Easy to insert and position
- Easy to clean and maintain
- Easy to use with unscented, colorless, stainless GYNOL II* (2% nonoxynol-9) Contraceptive Jelly
- The combination for continuation—with 4 out of 5 patients continuing after 1 year†

Continuation...it's one reason why physicians continue to make ORTHO ALL-FLEX and GYNOL II the #1 prescribed diaphragm combination in America.‡

Ortho ALL-FLEX*

Arcing Spring

DIAPHRAGM

†Number of patients continuing the method for 12 consecutive months; data on file, Ortho Pharmaceutical Corporation.

‡Data on file, Ortho Pharmaceutical Corporation.

Consult the patient brochure for information on toxic shock syndrome (TSS) and wearing time.

Weight gain by gestational age in both black and white women delivered of normal-birth-weight and low-birth-weight infants 801
Diana B. Petitti, MD, Mary S. Croughan-Minihane, PhD, and Robert A. Hiatt, MD, PhD
San Francisco and Oakland, California

Weight gain in black and white women delivered of infants who weighed ≥3000 gm was the same at every gestational age and was highly variable.

The effects of hormone replacement therapy in normal postmenopausal women: Measurements of Doppler-derived parameters of aortic flow 806
Amos Pines, MD, Enrique Z. Fisman, MD, Yoram Levo, MD, Mordechai Averbuch, MD, Arie Lidor, MD, Yaacov Drory, MD, Ariel Finkelstein, MD, Miriam Hetman-Peri, MD, Menachem Moshkowitz, MD, Efraim Ben-Ari, PhD, and Daniel Ayalon, MD
Tel Aviv, Israel

Initiation of hormone replacement therapy in healthy postmenopausal women was associated with an increase in stroke volume and aortic flow acceleration as measured by Doppler echocardiography.

Decreased levels of polyunsaturated fatty acids in preeclampsia 812
Yuping Wang, MD, Helen H. Kay, MD, and Allen P. Killam, MD
Durham, North Carolina

Patients with preeclampsia had decreased levels of polyunsaturated fatty acids (*n*-3 and *n*-6) as compared with patients with normal pregnancy; patients with normal pregnancy had increased levels of *n*-3 polyunsaturated fatty acids as compared with levels in nonpregnant patients.

Amniotic fluid glucose and intraamniotic infection 818
Brian Kirshon, MD, Bernard Rosenfeld, MD, Giancarlo Mari, MD, and Michael Belfort, MD
Houston, Texas

Reduced amniotic fluid glucose concentration in women with preterm labor or preterm premature rupture of membranes is associated with either intraamniotic infection or progression of labor.

Fetal breathing movements after preterm premature rupture of membranes 821
Alistair B. Roberts, MD, Israel Goldstein, MD, Roberto Romero, MD, and John C. Hobbins, MD
New Haven, Connecticut

Fetal breathing movements were significantly reduced for 2 weeks after membrane rupture, in patients with preterm premature rupture of membranes, between 24 and 34 weeks' gestation.

(Contents continued on page 14A)

Contents continued from page 13A

Outpatient sedation: An essential addition to gynecologic care for persons with mental retardation 825
David A. Rosen, MD, Kathleen R. Rosen, MD, Thomas E. Elkins, MD, H. Frank Andersen, MD, S. Gene McNeeley, Jr., MD, and Cheryl Sorg, RN
Ann Arbor, Michigan

In mentally retarded women refusing gynecologic examination, sedation in the outpatient setting allowed for the subsequent performance of a satisfactory pelvic examination in 81%.

Does unexplained second-trimester (15 to 20 weeks' gestation) maternal serum α-fetoprotein elevation presage adverse perinatal outcome? 829
Joe Leigh Simpson, MD, Sherman Elias, MD, Cynthia D. Morgan, RN, MS, Richard N. Andersen, PhD, Lee P. Shulman, MD, Baha M. Sibai, MD, and Amanda Skoll, MD
Memphis, Tennessee

Third-trimester maternal serum α-fetoprotein can be reproducibly assayed and may prove useful in predicting pregnancy complications and adverse perinatal outcome.

Cardiac function in fetuses of type I diabetic mothers 837
Giuseppe Rizzo, MD, Domenico Arduini, MD, and Carlo Romanini, MD
Rome and Ancona, Italy

In spite of an adequate metabolic control of pregnancy, fetuses of type I diabetic mothers show abnormalities of diastolic function that are proportional to the thickness of the interventricular septum.

Human placenta expresses endothelin gene and corresponding protein is excreted in urine in increasing amounts during normal pregnancy 844
Ariela Benigni, Biol.Sci.D., Flavio Gaspari, Chem.D., Silvia Orisio, Biol.Sci.D., Luca Bellizzi, Chem., Giuseppe Amuso, MD, Tiziana Frusca, MD, and Giuseppe Remuzzi, MD
Bergamo and Brescia, Italy

Endothelin gene is expressed by human placenta and endothelin urinary excretion is increased in normal pregnancy as compared with levels in nonpregnant women.

Combination antimicrobial therapy in the treatment of acute pelvic inflammatory disease 849
Daniel V. Landers, MD, Pal Wolner-Hanssen, MD, Jorma Paavonen, MD, Edwin Thorpe, MD, Nancy Kiviat, MD, Marilyn Ohm-Smith, MS, James R. Green, MD, Julius Schachter, PhD, King K. Holmes, MD, PhD, David A. Eschenbach, MD, and Richard L. Sweet, MD
San Francisco, California, and Seattle, Washington

This study compares (clinically and microbiologically) the two most commonly recommended combination antimicrobial regimens in the treatment of acute pelvic inflammatory disease.

Contents

Meconium-stained amniotic fluid: A risk factor for microbial invasion of the amniotic cavity 859

Roberto Romero, MD, Shuichi Hanaoka, MD, Moshe Mazor, MD, Apostolos P. Athanassiadis, MD, Robert Callahan, BS, Yu Chiung Hsu, MD, Cecilia Avila, MD, Jose Nores, MD, and Carlos Jimenez, MD

New Haven, Connecticut

Meconium-stained amniotic fluid is a risk factor for microbial invasion of the amniotic cavity in patients with preterm labor.

Mild fetal lateral cerebral ventriculomegaly: Clinical course and outcome 863

Bryann Bromley, MD, Fredric D. Frigoletto, Jr., MD, and Beryl R. Benacerraf, MD

Boston, Massachusetts

Fetuses with mild ventriculomegaly have a lower incidence of associated anomalies and a better outcome than fetuses with more severe ventricular dilatation.

Hospital setting and fetal death during labor among women at low risk 868

Leah L. Albers, DrPH, and David A. Savitz, PhD

Chapel Hill, North Carolina

National data for 1980 showed that the risk of intrapartum fetal death in low-risk women increased as the level of hospital for birth decreased.

Fetal ovarian cysts: Prenatal ultrasonography detection and postnatal evaluation and treatment 874

Israel Meizner, MD, Arie Levy, MD, Miriam Katz, MD, Abraham Jacob Maresh, MD, and Marek Glezerman, MD

Beer-Sheva, Israel

Fetal ovarian cysts were diagnosed by antenatal ultrasonography in 15 cases; in six patients the ultrasonographic evidence of torsion was surgically confirmed after birth.

A comparison of flurbiprofen, tranexamic acid, and a levonorgestrel-releasing intrauterine contraceptive device in the treatment of idiopathic menorrhagia 879

Ian Milsom, MD, Kerstin Andersson, MD, Björn Andersch, MD, and Göran Rybo, MD

Göteborg, Sweden

The efficacy of flurbiprofen, tranexamic acid, and a levonorgestrel-releasing intrauterine contraceptive device was compared in the treatment of idiopathic menorrhagia.

Position change and central hemodynamic profile during normal third-trimester pregnancy and post partum 883

Steven L. Clark, MD, David B. Cotton, MD, James M. Pivarnik, PhD, Wesley Lee, MD, Gary D.V. Hankins, MD, Thomas J. Benedetti, MD, and Jeffrey P. Phelan, MD

Salt Lake City, Utah, Houston and San Antonio, Texas, Seattle, Washington, and Los Angeles, California

Central hemodynamic response to position change was studied in 10 carefully selected patients during the third trimester and again post partum.

Current Development

Nonsurgical management of tubal pregnancy 888
M. Pansky, MD, A. Golan, MD, I. Bukovsky, MD, and E. Caspi, MD
Tel Aviv, Israel

The various methods of nonsurgical treatment of ectopic pregnancy are reviewed in view of the changing presentation of this common disease.

BASIC SCIENCE SECTION

Serum levels of inhibin in maternal and umbilical blood during pregnancy 896
Toru Tabei, MD, Kazuhiko Ochiai, MD, Yoshiteru Terashima, MD, and Naoki Takanashi, PhD
Kawagoe and Tokyo, Japan

Maternal serum levels of inhibin are high in early and late pregnancy; the rise in late pregnancy parallels that of 17β-estradiol, progesterone, and human placental lactogen but not human chorionic gonadotropin.

Restriction fragment length polymorphism analysis to study the genetic origin of complete hydatidiform mole 901
Tsang-Ming Ko, MD, Chang-Yao Hsieh, MD, Hong-Nerng Ho, MD, Fon-Jou Hsieh, MD, and Tzu-Yao Lee, MD
Taipei, Taiwan, Republic of China

Restriction fragment length polymorphism analysis showed that most of the complete hydatidiform moles were caused by fertilization of an empty egg by a duplicated haploid sperm.

Transplacental, amniotic, urinary, and fetal fluid dynamics during very-large-volume fetal intravenous infusions 907
Robert A. Brace, PhD, and Thomas R. Moore, MD
La Jolla, California

Vascular volume loading with saline solution to elevate ovine fetal vascular pressure, by 5 mm Hg caused 500 ml/hr of fluid to cross the placenta into the maternal circulation, suggesting that small changes in fetal vascular pressures may dramatically alter the filtration capacity of the placenta.

Enhancement of germ tube formation in *Candida albicans* by β-endorphin 917
Steven S. Witkin, PhD, and Aliza Kalo-Klein, PhD
New York, New York

β-Endorphin stimulates germ tube formation in *Candida albicans* when added to sera from ovulating women.

CALL FOR DETAILS

We've Been Giving Doctors A Hand For Over Twenty Years.

And they've given us a hand in designing and refining the best obstetrical vacuum delivery system available.

Over twenty years ago, the Mityvac vacuum delivery system was introduced to provide an alternative method of delivery assistance. In that time we've learned a great deal about our system from the professionals who use it, and have incorporated what we've learned into real product improvements. Today, Mityvac is regarded by many obstetric physicians as the safest, most dependable method of vacuum extraction.

The Mityvac Obstetrical Vacuum Delivery System offers benefits available with no other vacuum extraction system, like sensitive fingertip controls which allow the operator to adjust vacuum pressure to coincide with the natural efforts of the mother. In addition, the soft polyethylene extractor cup is flexible enough for ease of insertion, yet seals easily to the infant's scalp distributing tractive force across a large area. The Mityvac system offers greater control and insures minimal trauma to both infant and mother.

In vacuum extraction systems, Mityvac is the name that more obstetric physicians have come to know and depend on than any other. Mityvac. . . offering a hand for over twenty years.

The effect of volume expansion on placental blood flow in awake hypovolemic rats in late pregnancy 921
Peter F. Boekkooi, MD, Carla M. Verkeste, BSc, and Louis L.H. Peeters, MD, PhD
Maastricht, The Netherlands

Volume expansion in hypovolemic rats increases cardiac output but decreases uteroplacental blood flow.

Pharmacokinetics of pentamidine in Sprague-Dawley rats in late pregnancy 927
Bertis B. Little, MA, PhD, Timothy H. Harstad, MD, Roger E. Bawdon, PhD, Sohrab Sobhi, BS, Daniel A. Roe, BS, Kraig A. Knoll, BS, and Fred E. Ghali, BS
Dallas, Texas

Pharmacokinetics of pentamidine isethionate in timed-pregnant Sprague-Dawley rats were analyzed, and the drug was found in placental and fetal organs, including brain, kidney, and liver.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Prices include shipping. *Payment must accompany all orders and must be in U.S. funds, drawn on a U.S. bank.*

Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318 USA; phone (314) 453-4394. In the U.S., call toll-free: 1-800-325-4177, ext. 4394. Please allow six weeks for delivery.

The JOURNAL is abstracted and/or indexed in *Index Medicus, Science Citation Index, Current Contents/Clinical Medicine, Current Contents/Life Sciences, Excerpta Medica, BRS Colleague,* and MEDLINE.

Calcium every day
Aerobics every week
Bone loss every year

She needs PREMARIN to help prevent further bone loss

Calcium[1] and exercise are not enough to prevent post-menopausal osteoporosis, since estrogen deficiency is the primary cause.[2] PREMARIN is the only brand of estrogen indicated to prevent further bone loss and in a recently published study has been shown to reduce the risk of hip fractures by as much as 66%.[3]

Early PREMARIN therapy offers the best protection

The most significant rate of bone loss occurs in early menopause. PREMARIN can help maintain bone mass, preventing the progression of osteoporosis and its consequences.

Protection continues as long as estrogen therapy continues

Clinical studies show that within three years of menopause when therapy is withdrawn, bone loss begins again.[4]

PREMARIN®

(conjugated estrogens tablets)

Proven benefits for menopause and beyond

Estrogens have been reported to increase the risk of endometrial carcinoma in postmenopausal women. Estrogens should not be used in women (or men) with any of the following conditions: known or suspected 1) pregnancy, 2) breast cancer, 3) estrogen-dependent neoplasia, 4) undiagnosed abnormal genital bleeding, 5) active thrombophlebitis or thromboembolic disorders.

See important information on adjacent page.

For moderate-to-severe vasomotor symptoms and for osteoporosis

PREMARIN®
(conjugated estrogens tablets)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

The appearance of these tablets is a trademark of Wyeth-Ayerst Laboratories.

For atrophic vaginitis

PREMARIN®
(conjugated estrogens)

Vaginal Cream

0.625 mg/g

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULARS.)*

PREMARIN® Brand of conjugated estrogens tablets, USP
PREMARIN® Brand of conjugated estrogens Vaginal Cream, in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA. Close clinical surveillance of all women taking estrogens is important. Adequate diagnostic measures including endometrial sampling when indicated should be undertaken to rule out malignancy in all cases of undiagnosed persistent or recurring abnormal vaginal bleeding. There is currently no evidence that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.
2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY. Estrogen therapy during pregnancy is associated with an increased risk of congenital defects in the reproductive organs of the male and female fetus, an increased risk of vaginal adenosis, squamous-cell dysplasia of the uterine cervix, and vaginal cancer in the female later in life. The 1985 DES Task Force concluded that women who used DES during their pregnancies may subsequently experience an increased risk of breast cancer. However, a causal relationship is still unproven, and the observed level of risk is similar to that for a number of other breast cancer risk factors.

There is no indication for estrogen therapy during pregnancy. Estrogens are ineffective for the prevention or treatment of threatened or habitual abortion.

DESCRIPTION: PREMARIN (conjugated estrogens, USP) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters. Tablets are available in 0.3 mg, 0.625 mg, 0.9 mg, 1.25 mg, and 2.5 mg strengths of conjugated estrogens. Cream is available as 0.625 mg conjugated estrogens per gram.

INDICATIONS AND USAGE: Moderate-to-severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression which might occur during menopause and they should not be used to treat these conditions.) Prevention and management of osteoporosis (abnormally low bone mass). Atrophic vaginitis. Atrophic urethritis. Hypoestrogenism due to hypogonadism, castration or primary ovarian failure.

PREMARIN (conjugated estrogens) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected pregnancy (see Boxed Warning). 2. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 3. Known or suspected estrogen-dependent neoplasia. 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. Estrogen replacement therapy has not been reported to increase the risk of thrombophlebitis and/or thromboembolic disease. However, there is insufficient information regarding women who have had previous thromboembolic disease.

PREMARIN Tablets and Vaginal Cream should not be used in patients hypersensitive to their ingredients.

WARNINGS: Some studies suggest a possible increased incidence of breast cancer in women taking higher doses of estrogen for prolonged time periods. The majority of studies have not shown an association with usual estrogen replacement doses. Endometrial cancer risk among estrogen users was about 4-fold or greater than in non-users, and appears dependent on treatment duration and estrogen dose. In patients on combined estrogen-progestin therapy, this risk appears to be decreased. (See PRECAUTIONS below.)

Estrogen therapy during pregnancy is associated with an increased risk of fetal congenital reproductive tract disorders.

A 2.5-fold increase in the risk of surgically confirmed gall bladder disease in women receiving postmenopausal estrogens has been reported.

Large doses of estrogen such as those used to treat prostate and breast cancer have been shown to increase the risk of non-fatal myocardial infarction, pulmonary embolism, and thrombophlebitis in men. This cannot necessarily be extrapolated to women. However, to avoid theoretical cardiovascular risk caused by high estrogen doses, the doses for estrogen replacement therapy should not exceed the recommended dose.

Blood pressure should be monitored with estrogen use, especially if high doses are used.

Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: The addition of a progestin for 7 or more days of a cycle of estrogen administration reportedly lowers the incidence of endometrial hyperplasia. Studies of endometrium suggest that 10 to 13 days of progestin are needed to provide maximal endometrial maturation and elimination of hyperplastic changes. Additional risk, such as adverse effects on carbohydrate and lipid metabolism, may be associated with the inclusion of progestin in estrogen replacement regimens. The choice of progestin and dosage may be important in minimizing these adverse effects.

Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolaou smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention, such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding and mastodynia. Pre-existing uterine leiomyomata may increase in size during estrogen use. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, or metabolic bone diseases associated with hypercalcemia.

The following drug/laboratory test interactions have been reported, some only with estrogen-progestin combinations (oral contraceptives):

1. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.
2. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by T_4 levels determined by column or by radioimmunoassay. Free T_3 resin uptake is decreased, reflecting the elevated TBG; free T_4 concentration is unaltered.
3. Impaired glucose tolerance.
4. Reduced response to metyrapone test.
5. Reduced serum folate concentration

MUTAGENESIS AND CARCINOGENESIS: Long-term, continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver.

PREGNANCY CATEGORY X: Estrogens should not be used during pregnancy. See **CONTRAINDICATIONS** and Boxed Warning.

NURSING MOTHERS: As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy; changes in vaginal bleeding pattern and abnormal withdrawal bleeding or flow, breakthrough bleeding, spotting, increase in size of uterine fibromyomata, vaginal candidiasis, change in amount of cervical secretion; tenderness or enlargement of breasts; nausea, vomiting, abdominal cramps, bloating, cholestatic jaundice; chloasma or melasma that may persist when drug is discontinued, erythema multiforme, erythema nodosum, hemorrhagic eruption, loss of scalp hair, hirsutism; steepening of corneal curvature, intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea and vomiting.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of conjugated estrogens tablets, USP

1. *Given cyclically for short-term use only.* For treatment of moderate-to-severe vasomotor symptoms, atrophic vaginitis, or atrophic urethritis associated with the menopause (0.3 mg to 1.25 mg or more daily). The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible. Administration should be cyclic (eg, three weeks on and one week off). Attempts to discontinue or taper medication should be made at three- to six-month intervals.
2. *Given cyclically:* Hypoestrogenism. Osteoporosis.

Hypoestrogenism due to: Female hypogonadism—2.5 mg to 7.5 mg daily in divided doses for 20 days followed by 10 day rest period. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. Female castration or primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis—0.625 mg daily. Administration should be cyclic (eg, three weeks on and one week off).

PREMARIN® Brand of conjugated estrogens Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Attempts to discontinue or taper medication should be made at three- to six-month intervals.

Usual dosage range: 2 g to 4 g daily, intravaginally, depending on the severity of the condition.

Patients with an intact uterus who are treated with either PREMARIN Tablets or Vaginal Cream should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors*. Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than U.S. in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY

COPYRIGHT STATEMENT

Must be signed by ALL authors

"The undersigned author(s) transfers all copyright ownership of the manuscript entitled

to Mosby–Year Book, Inc., in the event the work is published. The undersigned author(s) warrants that the article is original; is not under consideration by another publication; and its essential substance, tables, or figures have not been previously published. This restriction does not apply to abstracts or press reports published in connection with scientific meetings. The author(s) confirms the final manuscript has been read and each author's contribution has been approved by the appropriate author."

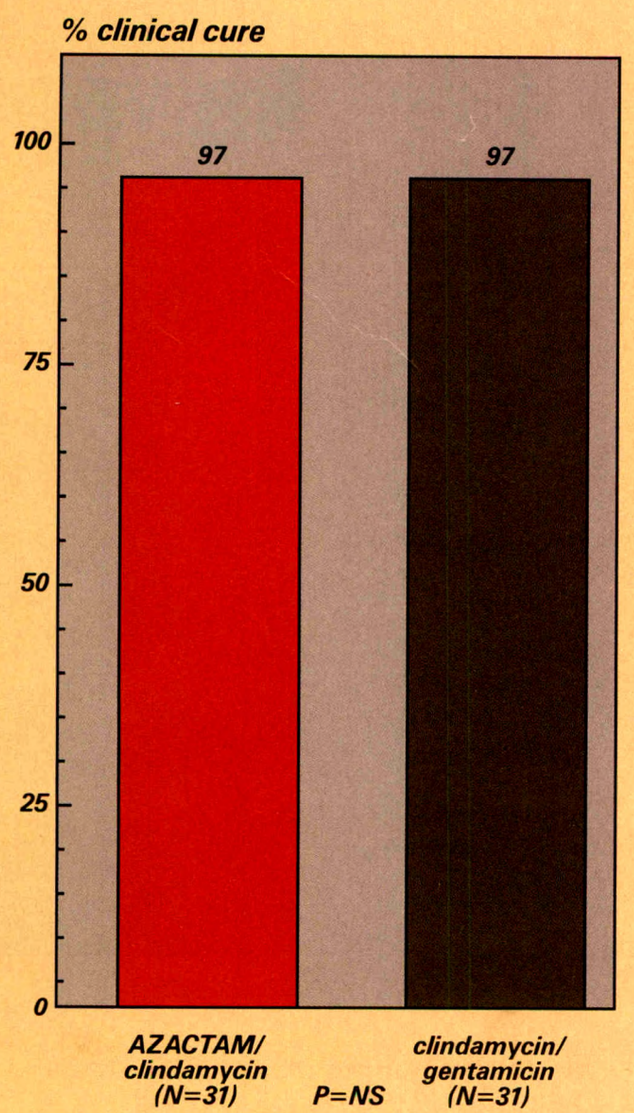
LAST YEAR, 4 DOCTORS GAVE UP PRIVATE PRACTICE FOR A CHALLENGING NEW CAREER.

They didn't give up medicine. They just started practicing it in a more exhilarating environment.

An environment that affords them many tangible benefits. Like a diverse practice, unlimited access to medical specialities, and financial security. Plus a lot of intangibles. Like a comfortable lifestyle, an opportunity for worldwide experiences and the respect that goes along with being an Air Force officer.



Of course, to enter an environment this rewarding, they did have to give up a few things. Like rent, equipment expenses, malpractice insurance, payrolls and utility bills.

Now, you may be intrigued by such a unique opportunity. But like any good medical professional, you'd probably like a complete case history. So call 1-800-423-USAF. Or send your curriculum vitae to Colonel William E. Patterson, United States Air Force/RSH, Randolph Air Force Base, Texas 78150-5421.

AIM HIGH.

AIR FORCE

IN POSTPARTUM ENDOMETRITIS*

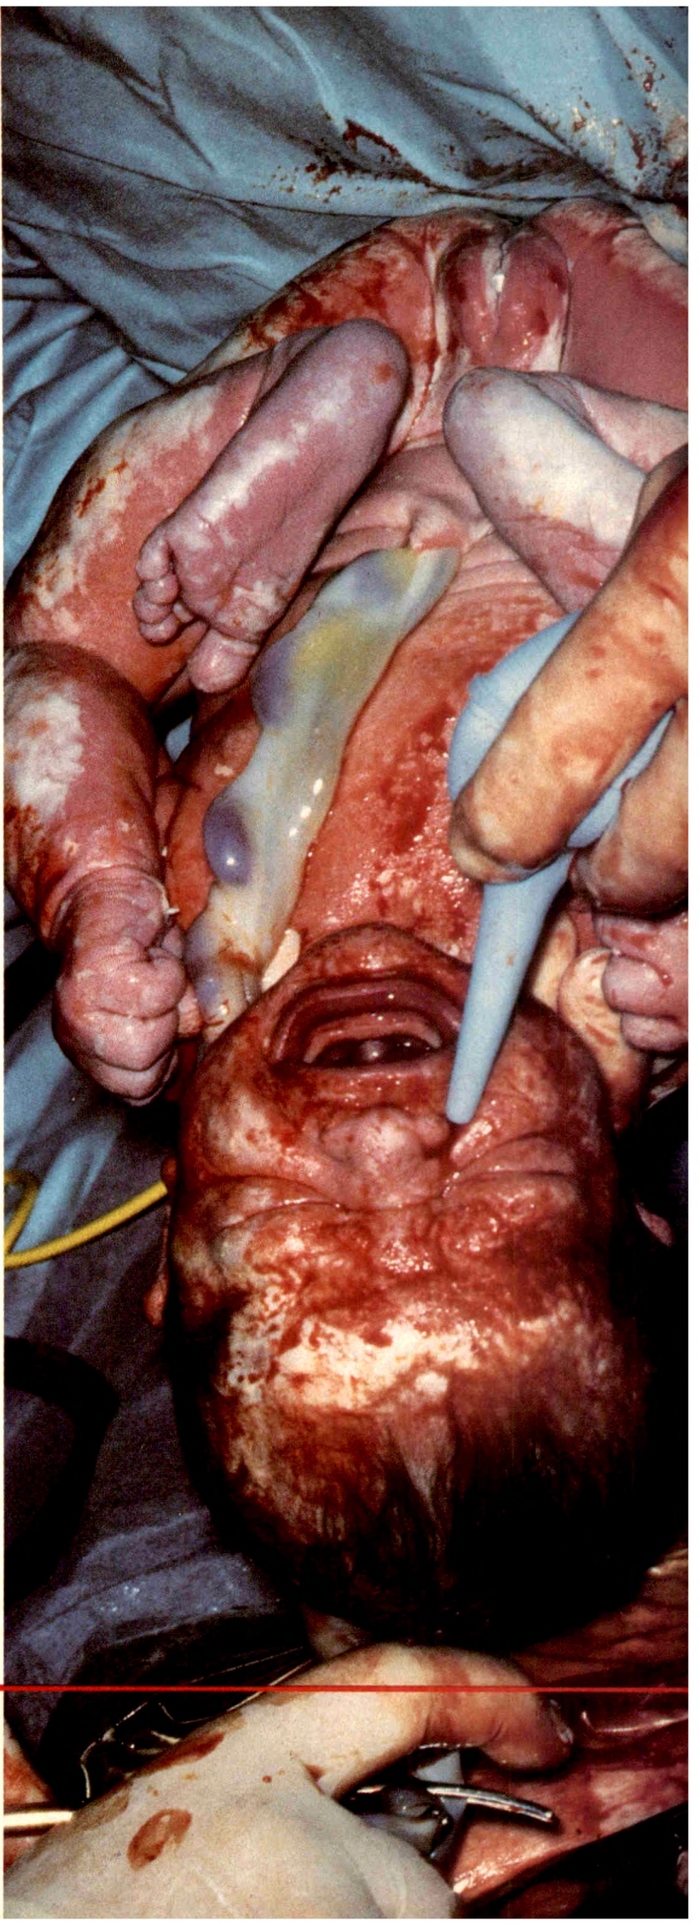
A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

Azactam®
aztreonam
delivers...

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.



‡Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.†*
- *Greater than 90% cure rates in combination with clindamycin.[1-3]*
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.‡*
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

Azactam®
aztreonam

A logical alternative to aminoglycosides.

Please see adjacent page for brief summary of prescribing information.

Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

EDITORIAL

Summary of analysis of published articles

September 1, 1989, through August 31, 1990

Each year a retrospective analysis of the articles published in the JOURNAL is presented to the readers and also to the Editorial Board and the Advisory Committee on Policy. Over the past twenty-one years we have compiled data on the classification, category, and type of articles accepted and published. A comparison of the data for the last two years is presented in Table I. A comparison of publication time in the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY of regular articles (excluding society articles) for 1985-1986 through 1989-1990 is shown graphically in Fig. 1, on page 710.* The pie charts on page 710 show the articles and page utilization for 1989-1990 by classification (Fig. 2A) and category (Fig. 2B).

*Publication time of regular articles from time of acceptance to publication: 1985-1986, 3.7 months; 1986-1987, 4.9 months; 1987-1988, 5.2 months; 1988-1989, 5.6 months; and 1989-1990, 5.1 months.

Maternal serum α-fetoprotein screening: Further consideration of low-volume testing

Daniel M. Strickland, MD,[a] Clifford A. Butzin, PhD,[b] and Frank H. Wians, Jr., PhD[c]
San Antonio, Texas

Unrecognized assay drift that may occur during low-volume (fewer than 500 specimens per week) maternal serum α-fetoprotein testing could result in either underestimation or overestimation of the number of pregnant women who are at increased risk of fetal malformations and genetic anomalies. Quality control software programs that incorporate the use of a multirule Shewhart chart are designed to detect assay drift. Careful selection of quality control sera for inclusion in analytic assays and appropriate application of a multirule quality control procedure to values that are obtained on these control materials should detect assay drift, regardless of the volume of patients' specimens in the run. (AM J OBSTET GYNECOL 1991;164:711-4.)

Key words: Maternal serum α-fetoprotein, low-volume maternal serum α-fetoprotein testing, neural tube defects, quality control

Since 1983, when the Food and Drug Administration first approved the use of α-fetoprotein kits for the detection of open neural tube defects, universal maternal serum α-fetoprotein screening for open neural tube defects, chromosomal anomalies (e.g., Down syndrome), and other congenital birth defects has expanded rapidly in the United States.[1, 2] The use of maternal serum α-fetoprotein concentration in screening for Down syndrome has expanded despite the fact that none of the commercially available kits for the performance of quantitative measurement of α-fetoprotein concentration are currently approved by the Food and Drug Administration for investigation of Down syndrome, and no kits are in the process of being reviewed for approval.[3]

Several aspects of maternal serum α-fetoprotein screening are controversial, such as cost-effectiveness, given the low prevalence of fetal open neural tube defects (1 to 2 cases per 1000 births) in the general obstetric population in the United States[4, 5]; weight correction of multiple of the median values[6-8]; use of a multiple of the median cutoff to investigate Down syndrome[9-14]; reporting of risk data for open neural tube defects, ventral wall defects, and Down syndrome[15, 16]; and the quality of maternal serum α-fetoprotein results from laboratories that perform low-volume testing.[17, 18] Macri et al.[17] have suggested that the quality of maternal serum α-fetoprotein test results that come from small, decentralized laboratories may be less than optimal because of the inability to identify and control assay drift with low-volume (i.e., <500 specimens per week) maternal serum α-fetoprotein testing. Interestingly, 64% of all laboratories that participated in the Maternal AFP [α-fetoprotein] Proficiency Survey (Set FP-D, 1989), which was administered by the American College of Pathologists, indicated a maternal serum α-fetoprotein volume of ≤50 specimens per week (Table I).

Assay drift occurs when analytic bias or imprecision causes a systematic change in assay performance, such that results are not accurate for analyte concentration that is obtained with an assay in which drift has occurred. In the case of maternal serum α-fetoprotein testing, unrecognized assay drift could result in either underestimation or overestimation of the number of pregnant women who are at increased risk of fetal malformations and genetic anomalies.[17]

Assay drift, in the context as discussed by Macri et al.,[17] can be either positive or negative, depending on whether the value for the mean multiple of the

median for all patients' samples in an individual maternal serum α-fetoprotein run or a series of runs (e.g., all runs during a 1-month period) lies above (positive drift) or below (negative drift) the limits of the 95% confidence interval, which was previously established with multiple of the median values of a large population. Low maternal serum α-fetoprotein weekly volume (i.e., <100 patients' specimens per assay, run five times per week) can result in a >47% probability that 10% assay drift (either positive or negative) will be undetected.[17] The solution to this problem that Macri et al.[17] propose is to establish regional programs for maternal serum α-fetoprotein testing with sufficient test volume to permit identification and control of assay drift.

If only patients' data from a particular analytic run are used to assess the presence or absence of assay drift, then estimation of the magnitude of type II error in the detection of assay drift involves the application of power analysis. A type II error would result in failure to detect assay drift, whereas a type I error would result in false identification of assay drift. Currently available quality control software programs are capable of detecting both of these types of errors.[19-21]

Most statistics textbooks (such as that of Winer[22]) refer to three determinants of the magnitude of type II error that are germane to the calculation of assay drift: the level of significance (i.e., type I error) that is used in hypothesis testing, sample size, and sample variance. The acceptable level of type I error is the most easily manipulated of these parameters because it is designated by the investigator before the hypothesis is tested. In general, however, if the magnitude of allowable type I error is decreased, then the type II error rate is increased.

Macri et al.[17] used a level of significance of 0.05 to develop the data that are presented in Table I of their article. If this level were to be relaxed to 0.10, the ability to detect assay drift would be improved significantly, but it would be at the expense of increased probability of false identification.

Macri et al.[17] discuss only the effect of sample size on the probability that assay drift will be undetected. Sample variance is equally important, however, because the lower the variability of assay results, the narrower the confidence interval around the mean multiple of the median that is determined from a large number of multiple of the median values that are obtained with this assay, and consequently, the probability that significant assay drift will be undetected is lower.

Although Macri et al.[17] do not provide data on the variance that was observed in their population of multiple of the median values, we estimate from their data that the ratio of their population mean (u) to the population standard deviation (s) was 1.7. With the use of multiple of the median data (n = 1406) from our laboratory over an 11-month period (two maternal serum α-fetoprotein runs per week or approximately 32 specimens per week), we obtained these values: u = 1.123, s = 0.485, and u/s = 2.32.

Thus data that were obtained from our laboratory with the Tandem-E α-fetoprotein assay (Hybritech Inc, San Diego, Calif.) to quantitate maternal serum α-fetoprotein levels and to establish reference range median maternal serum α-fetoprotein values for 15 to 20 weeks' gestational age in our obstetric population are less variable than those that are presented by Macri et al.[17] With our data for population mean, standard deviation, population mean divided by standard deviation and a specimen volume of fewer than 30 patients' samples per assay, we calculated an 18% probability of missing 20% assay drift (either positive or negative), whereas at this specimen volume, Macri et al.[17] calculated a >38% probability of missing 20% assay drift. More importantly, Best[23] has shown that an improvement in assay precision results in higher detection efficiency for open neural tube defects, fewer false-positive results, a reduction in the number of follow-up procedures, and an overall decrease in the cost of maternal serum α-fetoprotein testing to the patient.

Hullin et al.,[24] who routinely perform assays for maternal serum α-fetoprotein concentration for a minimum of 120 patients' samples per week, have suggested that patients' data plotted in CUSUM (cumulative sum) form can also provide an early warning of potential problems in the maternal serum α-fetoprotein screening program. Thus assay drift can be detected, even with relatively low-volume maternal serum α-fetoprotein testing.

Moreover, commercially available quality control software programs, which are routinely used by many clinical laboratories, incorporate the use of a multirule Shewhart chart to reduce the probability of false re-

jection of a run when the analytic method is in fact stable and to increase the probability of error detection.[19-21] The types of errors that these quality control programs are designed to detect include assay drift, which causes a systematic analytic error, and an increase in the standard deviation, which causes an increase in the random analytic error of the method.[20] Thus careful selection of quality control sera for inclusion in analytic assays and appropriate application of a multirule quality control procedure to values that are obtained on these control materials should detect assay drift, regardless of the volume of patients' specimens in the run.

High-volume maternal serum α-fetoprotein testing, however, as pointed out by Marci et al.,[17] is usually more cost-effective, especially when immunoassay methods that require several calibrator and control samples with each assay are used. In addition, centralization of maternal serum α-fetoprotein testing in a few regional centers that specialize in providing patient-specific risk data that are relevant to open neural tube defects, ventral wall defects, Down syndrome, and other chromosomal anomalies is likely to enhance the quality of the information that is provided by these centers as compared with that provided by small laboratories with a much smaller maternal serum α-fetoprotein data base and larger workload concerns.

Recently, we and others have advocated centralized maternal serum α-fetoprotein testing among military medical treatment facilities by establishing regional centers to perform this testing.[25, 26] It is our opinion that the advantages of regional maternal serum α-fetoprotein screening programs go beyond simply increasing specimen volume sufficiently enough to be able to identify and control assay drift.

The cost of maternal serum α-fetoprotein testing by commercial reference laboratories can vary between $18 and $45 per test, compared with approximately $9 per reportable patient's result in our laboratory.[26] Thus we achieved a savings of $9 to $36 per maternal serum α-fetoprotein test. We have suggested previously that this savings could be increased further, if regionalized maternal serum α-fetoprotein testing were to be established for all Department of Defense medical treatment facilities.[26]

Thus high-volume maternal serum α-fetoprotein testing may be desirable more on the grounds of cost-effectiveness and consolidation of clinical data than for detection of assay drift. Until regional centers are established for performance of this testing, however, the application of stringent quality control practices and adherence to the guidelines that have been suggested by Milunsky and Haddow[27] and by Knight et al.[2] for evaluation of the quality of maternal serum α-fetoprotein screening programs will increase the probability of obtaining accurate and reliable results in laboratories that perform low-volume maternal serum α-fetoprotein testing.

As pointed out by Dr. H.B. Soloway,[5] "FDA should not be concerned with how many [maternal serum α-fetoprotein] tests a lab performs, but rather how often it gets the right result. . . . The FDA notion that bigger is better is as fallacious in respect to laboratory testing as it is in respect to Federal bureaucracies."

Posterior colporrhaphy and perineorrhaphy: Separate and distinct operations

David H. Nichols, MD
Providence, Rhode Island

Posterior vaginal repair is often poorly understood and ineffectively performed. The goals of reconstructive surgery emphasize relief of symptoms and restoration of normal anatomic relationships and of function. A useful method to preoperatively determine posterior vaginal wall weakness is outlined along with a surgical description of important steps in surgical reconstruction. (Am J Obstet Gynecol 1991;164:714-21.)

Key words: Posterior colporrhaphy, rectocele, perineorrhaphy, defective perineum, posterior vaginal repair

Posterior repair is generally among the most misunderstood and poorly performed common gynecologic surgical procedures. Some of the dissatisfaction relates to the failure to relieve the patient's referable symptoms and the production of significant postoperative dyspareunia.

Although rectocele is fairly common among multiparous women, there is considerable confusion and divergence of opinion concerning not only the related symptoms and indications for repair, but also the anatomic goals sought by the repair and therefore the specific techniques of repair used to achieve them. Rectocele and perineal defect are anatomically separate, but they may coexist (Fig. 1). Each may be repaired when symptomatic, but by quite separate and distinctive surgical procedures. Rectocele is fundamentally a defect of the vagina and its supports, not of the rectum. The symptoms of rectocele are primarily inability to completely empty the bowel, often requiring manual vaginal or perineal expression to complete evacuation and often followed by postevacuation rectal discomfort, probably related to venous congestion consequent to straining. Constipation, per se, is not a symptom of rectocele, although it may coexist. There are many constipated women without rectocele, many women with rectocele who are not constipated, and some women with constipation who have rectocele. Surgical repair of rectocele will not necessarily relieve constipation, the latter being more likely a disorder in bowel habits and function, but not necessarily of anatomy.

A gaping perineum, a result of perineal defect, may at times subtract from coital satisfaction, and this may be improved by perineorrhaphy. The latter will not convert or correct a marital discomfort that is a result

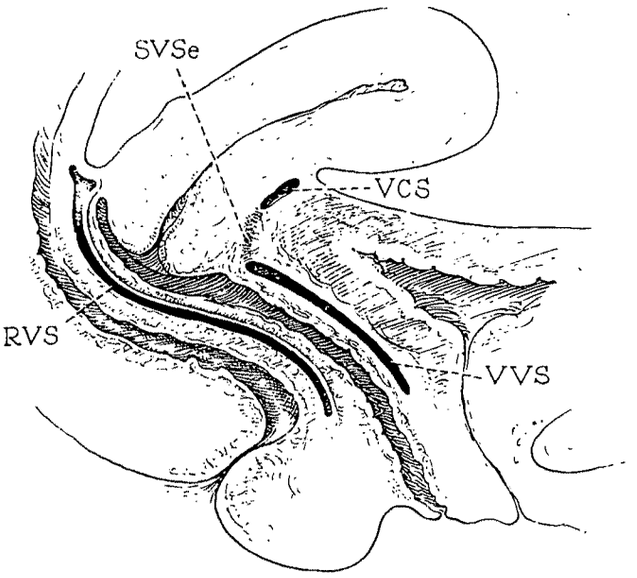

Fig. 2. Rectovaginal space *(RVS)* is shown between rectum and vagina, extending from perineal body to bottom of cul-de-sac of Douglas. Rectovaginal septum is a condensation of tissue attached to underside of posterior vaginal wall along with full length of rectovaginal space. Supravaginal septum *(SVSe)*, vesicocervical space *(VCS)*, and the vesicovaginal space *(VVS)* are shown. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:34. By permission.)

of other unrelated interpersonal dissatisfactions or conflicts. The goals of reconstructive surgery are relief of symptoms, restoration of anatomy, and restoration of function.

The normal anatomy of the posterior vaginal wall is shown in Fig. 2. The "S-shaped" curve of the vagina ends just in front of the hollow of the sacrum. The vagina is separated from the rectum by the avascular

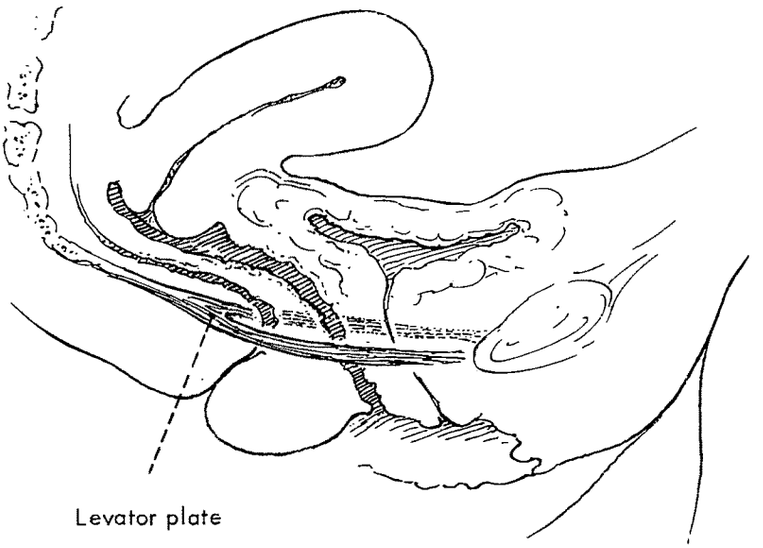

Fig. 3. Normal axis is shown. Notice the almost horizontal upper vagina and rectum lying on and parallel to levator plate. Latter is formed by fusion of pubococcygei muscle posterior to rectum. (Reprinted with permission from The American College of Obstetricians and Gynecologists. Nichols DH, Milley PS, Randall CL. Significance of restoration of normal vaginal depth and axis. Obstet Gynecol 1970;36:251-6.)

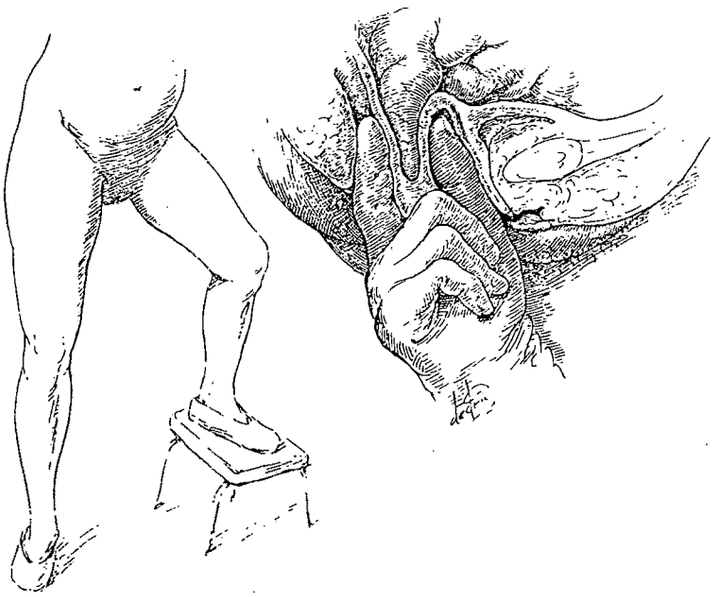

Fig. 4. Examination of patient in standing position permits thumb in vagina to note and replace any descent of vaginal vault while index finger introduced into rectum permits evaluation of any possible rectocele. When patient strains, any enterocele present is evidenced by palpation of bowel-filled sac dissecting the rectovaginal septum. (From Nichols DH. Repair of enterocele and prolapse of the vaginal vault. In: Barber H, ed. Goldsmith's practice of surgery. Danbury, Connecticut: Cine-Med. Copyright 1981, Cine-Med. By permission.)

rectovaginal space, which permits the rectum and vagina to function independently of one another and therefore should be preserved after reconstructive surgery. There is a thin membrane-like connective tissue called the fascia of Denonvilliers that is fused to the underside of the posterior vaginal wall.[1] It extends downward from the bottom of the cul-de-sac of Douglas to its attachment to the upper margin of the peri-

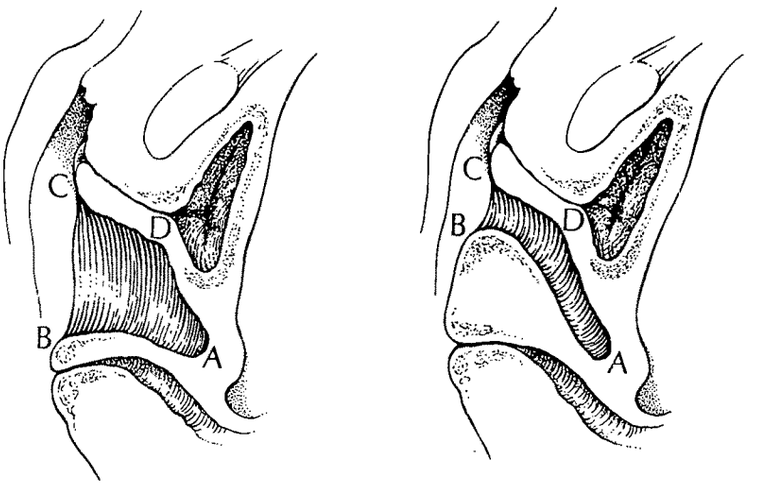

Fig. 5. Effect of perineorrhaphy on lengthening the posterior vaginal wall is shown. Sagittal drawing of pelvis of patient with defective perineum is at *left.* Anterior vaginal wall *(ADC)* is longer than posterior wall *(AB).* Lengthening of posterior vagina *(AB)* after perineorrhaphy is shown at *right.* Length of anterior vaginal wall *(ADC)* is unchanged. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:293. By permission.)

neal body. When this caudal attachment is avulsed, the perineum is destabilized, and such weakness here is one cause of low rectocele. Reattachment should be achieved surgically. The fascia of Denonvilliers has sufficient strength that it may be used effectively during posterior colporrhaphy.[2] It represents a peritoneal fusion layer of the obliterated extension of the pelvic cavity and its lining peritoneum that during fetal development extended to the perineal body. Failure of fusion gives rise to a congenital deepness of the cul-de-sac in adult life, and when filled with bowel constitutes congenital enterocele.

Because failure of fusion thins the fascia of Denonvilliers, it also weakens the overlying posterior upper vaginal wall, a weakness conducive to high rectocele and accounts in part for the frequent coexistence of high rectocele with enterocele. So frequent is this association that when one is found the other must be routinely sought and usually repaired at the same time, lest it progress and become symptomatic and require subsequent surgery.

The axis of the upper vagina is more or less horizontal. This is because the upper vagina rests on a usually empty rectum, which in turn lies more or less passively on the levator plate, the latter a fusion of the right and left pubococcygei posterior to the rectum (Fig. 3). When the pelvic diaphragm is intact, it is itself in a horizontally oriented plane. Very few fibers of the pubococcygei decussate anterior to the rectum. The lateral walls of the vagina at its midportion are indirectly attached to the pubococcygei by the connective tissue fibers of Luschka. Therefore techniques of the posterior repair that emphasize primarily a bringing together of the levators between the vagina and rectum are essentially unanatomic. Ridges and painful muscular fibrosis from these levator stitches account for most of the postsurgical dyspareunia or apareunia reported by Jeffcoate.[3] He advised against posterior repair unless significant damage was confirmed by examination of the unanesthetized patient (because anesthesia effectively paralyzes the voluntary muscles of the pelvis, rendering a false idea of anatomic weakness from examination of the anesthetized patient).

Why, then, is there so much use of the Halban-Hegar prerectal levator plication? It must be remembered that in the days before intraperitoneal surgery and hysterectomy became surgically safe, the treatment of symptomatic uterine prolapse was by the wearing of an intravaginal pessary. When, after a time, the genital or levator hiatus became progressively more widened, the patient could not longer retain the pessary and the patient, now older, was worse off than ever. The introduction around the turn of the century of levator plication as a feature of perineorrhaphy enabled the patient to retain a vaginal pessary because the plication narrowed the levator or genital hiatus. Often, the only treatment that could be offered the patient was that of complete obliteration of the vagina as by Lafort colpocleisis.

Pessary use was gradually abandoned when vaginal hysterectomy became safer and a popular treatment of prolapse, and the erroneous concept was embraced that suggested that a firm perineum functioned as a "cork in the neck of a bottle" and that perineorrhaphy itself would retard or prevent uterine prolapse. Kelly[1] had previously observed the untruth of this view, noting

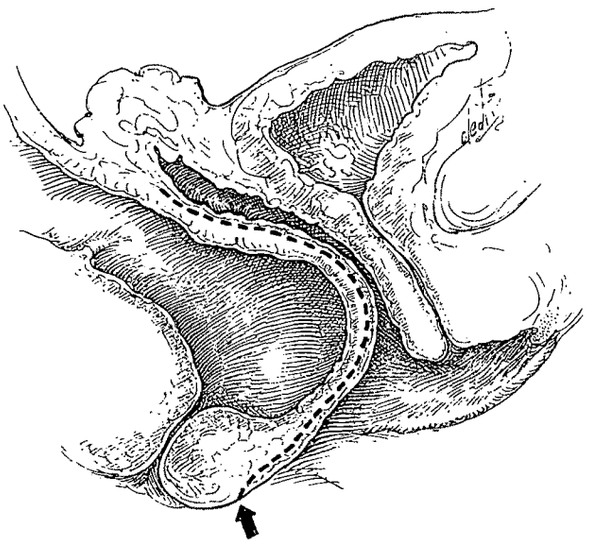

Fig. 6. Sagittal section shows initial line of dissection exposing full perineum and rectocele. Above the perineum, dissection enters rectovaginal space and continues proximal to highest point of rectocele, as indicated by *dashed line.* (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989. By permission.)

that uterine prolapse was uncommon among the many women he had seen who had long before suffered unrepaired complete perineal tears.

Rectocele and perineal defect may develop from rapid or overdistention of a poorly elasticized vaginal wall during labor. Such lack of elasticity may be predicted as a feature of aging among primigravid women older than 25 years and among persons with many wide striae that imply a very low elastic index.[5] The risk of rectocele may be lessened for such a patient by early and adequate episiotomy. Weakness of the posterior vaginal wall may also develop coincident to eversion of the vaginal vault, sharing or avulsing the fibers that attach the vagina to the pelvic diaphragm. This displacement of the vagina creates a weakness into which the anterior rectal wall may expand—another cause of rectocele.

Preliminary physical examination of the pelvis of the unanesthetized patient should attempt to find correlation between the patient's symptoms and anatomic disorder. With rectocele the examiner, during rectal examination, can always hook a finger into the pocket in which fecal material may become trapped. When coincident and generally unsuspected but contributory prolapse of the vaginal vault is determined by pelvic examination of the patient while she is standing and straining (Fig. 4), appropriate colpopexy should be included in the surgical plan.

Because the length of the perineal body is the same as that of female urethra, reconstruction of a damaged perineum will improve urethral support and function. It is interesting that perineorrhaphy will also lengthen the vagina by the mechanism shown in Fig. 5. With this in mind, we have for years used an anatomically correct reconstructive technique for posterior colporrhaphy and perineorrhaphy to achieve the goals described. Long-acting synthetic polyglycolic acid-type suture is used throughout, and if postmenopausal the patient is started preoperatively on a course of intravaginal estrogen replacement with an estrogen cream. This is continued for several months postoperatively. It will restore and improve vaginal elasticity, and by increasing the vaginal blood supply and thickening the vagina it promotes better wound healing. If a significant prolapse of the vaginal vault is found during examination, it should be repaired as should any coexistent enterocele.

Dissection and repair of the rectocele should begin at its highest point (Fig. 6). Because the perineal body is shaped essentially like a pyramid with its widest point or base at its bottom, the undersurface of the perineal body is uncovered by a V-shaped incision. The width of the V is determined by the desired size of the introitus at the conclusion of the operation, being careful to leave it a little loose for the aging patient so that it may not constitute a coital obstruction (Fig. 7). The dissection is carried beneath the posterior vaginal wall, separating it from the vaginal surface of the perineal body, until the rectovaginal space is identified and opened. A strip of an appropriate width of full-thickness posterior vaginal wall is removed, sufficient to relieve the rectocele and at the same time leave a normal-sized vagina diameter, one able to admit three fingerbreadths after the conclusion of the procedure. The sides of the posterior vaginal wall are approximated by a single layer of subcuticular sutures that incorporate the fascia

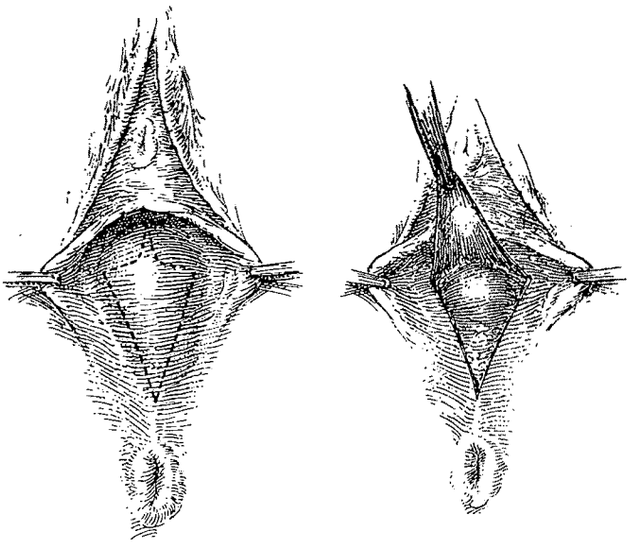

Fig. 7. Diamond-shaped piece of tissue of appropriate width is estimated as indicated in drawing at *left*. Skin is incised and dissection carried superiorly into vagina, exposing full site of future perineal body. If rectocele is present, rectovaginal space is entered, and the dissection freeing rectum from vagina carried to level above any rectocele that is present. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:288. By permission.)

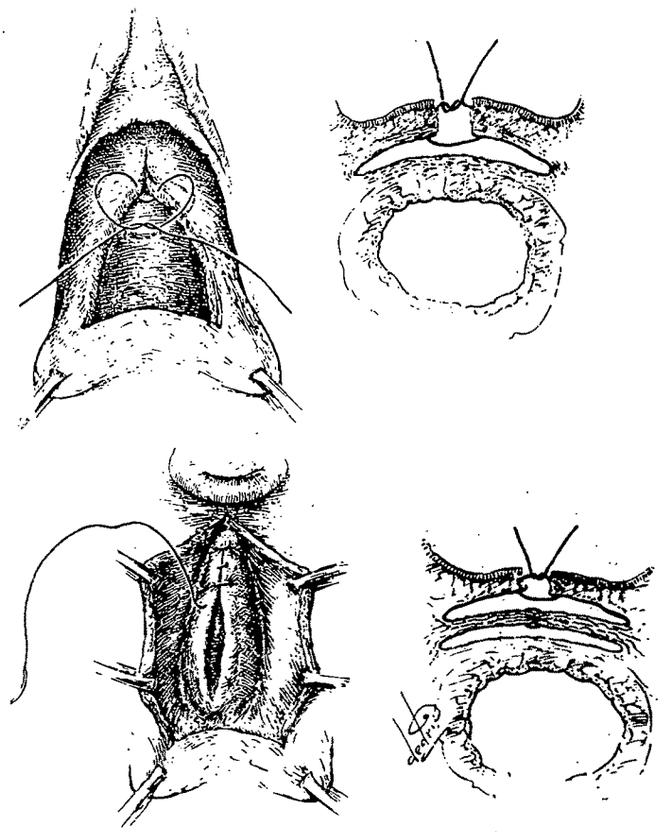

Fig. 8. In the Goff method of posterior colporrhaphy, appropriate full-thickness wedge of posterior vaginal wall is excised and tissues including fused rectovaginal septum are closed from side-to-side as noted in *upper portion* of illustration. Bullard modification is shown *below*, in which rectovaginal septum is dissected from posterior vaginal wall and closed as separate layer between rectum and vaginal membrane. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:282. By permission.)

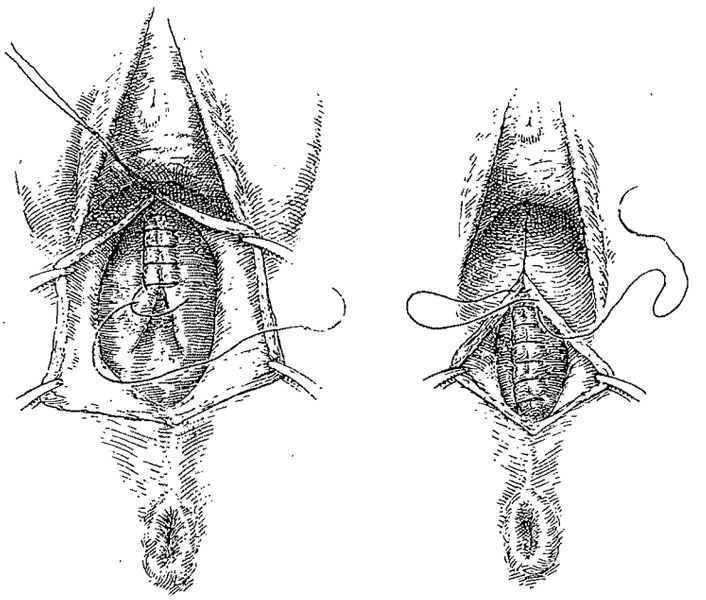

Fig. 9. Any ballooning of anterior rectal wall may be corrected by one or more layers of running or locked absorbable suture commencing proximal to defect and continuing distally for its full length. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:279. By permission.)

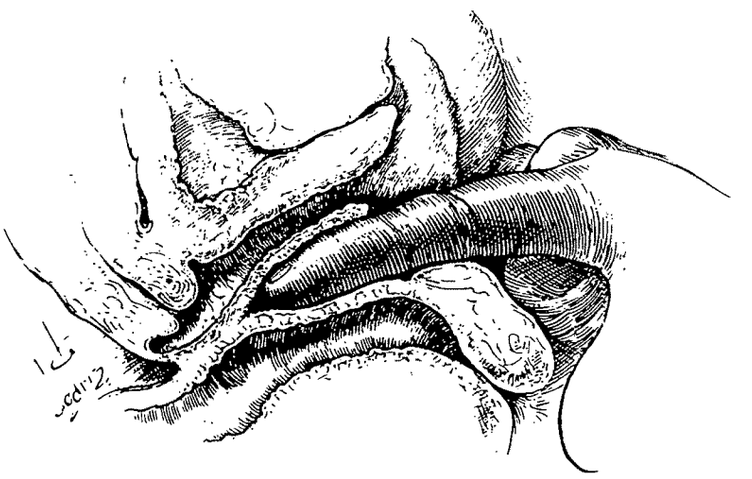

Fig. 10. At completion of posterior colporrhaphy and before starting perineorrhaphy, operator should be able to insert an index finger freely between posterior vaginal wall and anterior surface of rectum, showing desired freedom of this rectovaginal space. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:283. By permission.)

of Denonvilliers. Alternately the rectovaginal septum (the fascia of Denonvilliers plus a little of the posterior fibromuscular layer of the vagina) may be dissected from the undersurface of the vagina and closed as a separate layer (Fig. 8). Any secondary ballooning of the anterior rectal wall may be corrected by a running locked suture (Fig. 9) extending to the cranial margin of the perineal body. At the conclusion of the procedure and before the perineorrhaphy, the operator should be able to insert a finger into the rectovaginal space to show its freedom (Fig. 10).

The perineal body is reconstructed by a series of horizontal mattress sutures placed in the soft tissues medial to the pubococcygei as shown in Fig. 11. When

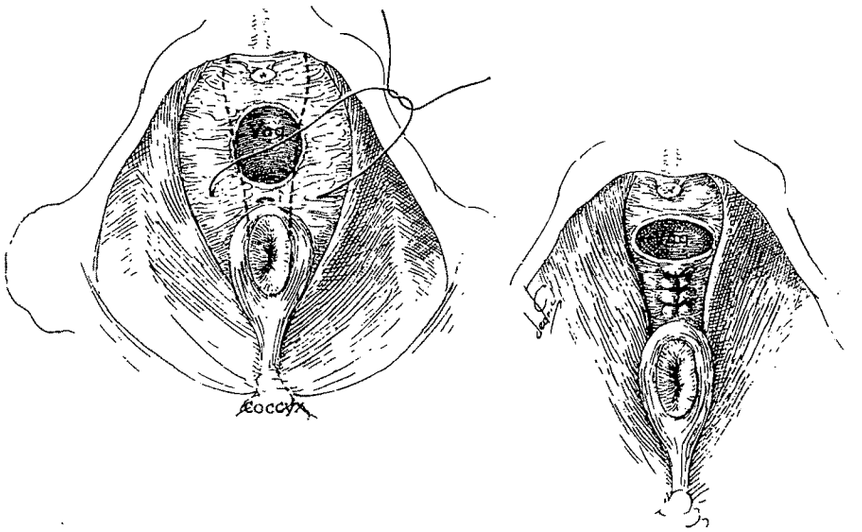

Fig. 11. Perineorrhaphy may be accomplished without placement of stitches directly into muscle bellies of pubococcygei, as shown with wide genital hiatus at *left*. When interrupted stitches in perineal body are tied, lateral attachments of this tissue to fascia of pubococcygei will bring latter closer together, narrowing genital hiatus to new position as noted by *dotted line*. End result is illustrated at *right*. Genital hiatus is effectively narrowed. No stitches were placed directly into muscular substance of pubococcygei. (From Nichols DH, Randall CL. Vaginal surgery. 3rd ed. Baltimore: Williams & Wilkins, 1989:291. By permission.)

these are tied, the levator-genital hiatus will have been effectively narrowed without stitches placed directly into the muscular substance of the pubococcygei. However, levator stitches may be used in the uncommon situation in which there is an extreme perineal defect and no other soft tissues can be found that can be brought together. When levator stitches are used, the operator should check for ridge production after each stitch is placed. If a ridge is found, the stitch is removed and replaced by a stitch located closer to the rectum. Levator stitches should never be tied tightly, lest they destroy the muscle in which they have been placed, converting it to often-tender fibrous tissue that may require future secondary perineotomy for relief. The perineal skin is reapproximated in the midline by a running subcuticular suture. The caliber or width of the vagina is assessed carefully with consideration to future coital satisfaction. If unexpectedly constricted, appropriate full vaginal thickness lateral relaxing incisions are made at the 3 o'clock and 9 o'clock positions. Rectal examination is done to confirm the integrity of the rectum; if a transgressing stitch is found, it is cut on the rectal side, lessening the postoperative pain and risk of rectovaginal fistula, and the suture is allowed to retract.

After surgery, the patient is placed on stool softeners and gentle laxatives to avoid straining at stool against the fresh repair. Ascorbic acid is given for a month or longer to promote wound healing, and postoperative estrogen supplementation is given if the patient is postmenopausal. Coitus may be resumed after 4 to 6 weeks of healing.

We adapted these techniques[6] from the works of our forebearers[7] and have used them with modifications for more than 40 years. They are anatomically and functionally correct, and neither postoperative dyspareunia nor obstructive apareunia has been observed.

Stratification and standards: A quality assurance perspective

Presidential address

Stanley Zinberg, MD
New York, New York

A diminished public respect for physicians, a decrease in professional autonomy, and an increased regulatory presence have led to extensive changes in medical practice in the past 25 years. Along with rising costs of medical care, there has been a resurgence in interest in the quality of health care, and a considerable body of literature on the monitoring and evaluation of health services has been produced. Quality assurance programs frequently evoke negative and skeptical responses from many physicians for a variety of reasons. Crucial to the potential effectiveness of quality assessment methods is the setting of standards. Physician clinicians should be strongly encouraged to participate directly and seriously in the development of standards. The quality assurance process should be viewed by physicians as an opportunity to recapture the control of the profession and to demonstrate to patients, in an objective manner, the legitimate high quality of care rendered. (AM J OBSTET GYNECOL 1991;164:722-8.)

Key words: Quality assurance, medical practice, standards, stratification

You had to live—did live, from habit that became instinct—in the assumption that every sound you made was overheard, and, except in darkness, every movement scrutinized.

George Orwell, *1984*

The year 1984 has come and gone and, for most Americans, George Orwell's fictional account of a world of totalitarian control appears not to have come to pass. How many of us involved in medical practice would agree? A Rip Van Winkle scenario that uses 1965 to 1990 as the period of hibernation would cause even a casual observer to concede that there have been extensive changes in the way physicians practice medicine.

These changes can be illustrated by listing six reasons why gifted college students chose to apply to medical school in the years since World War II. Headed by an interest in science and biology and the personal satisfaction derived from providing an important service to individuals and society, the future physician was aware of the prestige and respect that accompanied a career in medicine. Professional autonomy was automatically present and financial security and a wide choice of lifestyles were guaranteed.

Interest in the biological sciences and the opportunities to help people, which are the essence of the profession, have not diminished and continue to attract prospective physicians. Expanded medical information permits more effective patient treatment than in the past. However, public respect for physicians has weakened in the last two decades and, although this appears to be part of a general diminished public confidence in all American institutions (of which medicine suffers the least), the adverse impact on the doctor-patient relationship has been disheartening.[1] Professional autonomy is disappearing, and government agencies, insurance companies, and consumer groups question medical decisions and often dictate the course of treatment. Previously, the life-styles of physicians were determined by specialty and geographic location. Currently, regulatory groups are creating guidelines, incentives, and disincentives to control the number of physicians who enter specialities and to resolve a geographic maldistribution problem. Physicians' earnings are influenced by government, insurance companies, and a variety of health maintenance organizations.

In spite of a higher technical sophistication of ser-

vices, patients balk at the rising level of physicians' charges, which increase annually at a rate that exceeds inflation. Although these same patients recognize the physician's commitment of resources to the arduous study and practice of medicine, they perceive the health care commodity as an entitlement, and they resent paying for the misery of an illness that they did not request and over which they have no control, especially when they view the fees as excessive. To stoke the fire, a malpractice litigation problem of absurd proportions affects the traditional bond between doctor and patient. Dr. Saul Radovsky[2] wrote that "A final offsetting factor is the [disaffection] of doctors. Having believed themselves to be highly regarded by the public and having considered themselves to be exercising professional and economic responsibility in a calling, they now see themselves cast as wrongdoers and incompetents who yearly require new laws, regulations, admonitions, court decisions and exposés to make them more honest, ethical, competent, corrigible, and contrite. Perhaps it is no wonder if many now look for a change or an exit."

The temptation to link current circumstances of physician discontent to a decrease in the number and quality of medical school applicants is hard to resist. From a historical peak of 42,624 applicants in 1974, the applicant pool had decreased to 26,721 in 1988. The greatest decrease in applications was among white males but, in 1985, it was noted for the first time that the decrease included women and underrepresented minorities.[3] A demonstration of a decrease in quality of the applicant pool is more problematic, and the Medical College Admission Test results showed no significant changes, except possibly in the reading section. In 1981, 3.6% of applicants and 5.6% of matriculants scored 12 or greater, while in 1988 only 2.8% of applicants and 3.7% of matriculants achieved the same score in that section.

The significant event that led to the current situation was the passage in 1965 of the Medicare Act, which provided medical coverage for 20 million Americans and cost $4.5 billion in 1967; by 1985, it covered 30 million aged and disabled individuals and cost $70 billion for a program that provided less coverage than it had 18 years earlier. The central issue is money. In 1977, the nation's health care bill amounted to $160 billion, or 8.6% of the gross national product. In that year, for the first time, health care outstripped the costs for national defense and became the country's third largest industry, after agriculture and construction. In 1990, 13 years later, the nation's health bill is estimated to be $661 billion, which is currently 11.4% of the gross national product.[4] Of this $661 billion, $137 billion (21%) will be for physician services and $252 billion (38%) will be for hospital billings. Government, through its tax revenues, pays for more than 40% of all health care expenditures; the health bill for the federal government alone in 1989 was $114 billion; $24 billion of this was spent in medicare payments to physicians. One can take the view that not enough is being spent on health care and that 11% to 12% of a nation's gross national product spent on health is appropriate. Perhaps so! However, there appears to be little enthusiasm for this view from government, corporate America, or the citizenry at large. The federal government is currently the single greatest consumer of health care services, and it has often been said, "He who pays the piper, calls the tune." And the song we hear played so often goes like this: "Too much is being spent on health care. Does it need to cost so much? How do we know we are getting value for our money?"

This leads me to the principal theme: society's efforts to impose accountability on the individuals and institutions that provide health care services. This process has been euphemistically called quality assurance, and it is my thesis that the way in which physicians respond to the challenges created by this process will determine whether medical practice continues to be an academic, effective, and compassionate calling. We, as professionals, must define our standards, assess the results of our efforts, and judge the quality of our activities. This must not be left to others. Further, the proliferating quality assurance requirements, which at times tend to suffocate us, are probably our best and only opportunity to recapture the control of our profession and to restore the autonomy essential for attracting talented future physicians and for ensuring the best patient care.

The resurgence of interest in the quality of health care stems from increased government spending, rising costs of medical care, and rapid advances in medical science. There is agreement that the current interest in quality is largely finance driven, and it would be fantasy to believe that government and industry would be as preoccupied with quality level if these services were inexpensive. However, there are other considerations that stimulate this interest, such as instances of demonstrated poor level of care, increased consumer expectations, a rise in malpractice suits, and the proliferation of the variety of service institutions in which medical care is provided.

Historically, two basic principles of quality assurance were attributed to Hippocrates and Maimonides. Hippocrates wrote: "When there are procedures which can be right or wrong, a consideration of these must constitute a science. There is no science when there is neither a right way or wrong way." In 1198 AD Maimonides wrote the forerunner of the second opinion: "One should know that even if attended by a well-known physician, or several physicians, he should not submit, and take the strong remedies except on the advice of a physician who is very accomplished, whose knowledge has been verified, and whose experience has been attested."

In the early 1900s the Clinical Congress of Surgeons of North America developed a system for the evaluation of hospitals. The American pioneer in quality assurance was a Boston surgeon, Dr. Ernest Amory Codman,[5] who influenced the Clinical Congress of Surgeons to implement his method of end results analysis in its evaluation of hospitals. In 1916 he described issues similar to those used today to evaluate quality of surgical care, which included licensure and certification of physicians, accreditation of institutions, severity and stage of disease, comorbidity, patient behavior, and economic barriers to care. Six years before his death, in a largely autobiographic preface, he wrote: "I have suffered from a sense of isolation, because I have always been thinking, or saying, one thing or another, with which other doctors did not agree."

The American College of Surgeons, which was founded in 1913, inaugurated its Hospital Standardization program in 1918, and the concept of hospital accreditation was promoted as a means of assuring good care. Codman's exacting end-result methodology was set aside, and, instead, the American College of Surgeons published the "Minimum Standard," a one-page document, which did not assess outcomes of care but rather addressed structural measures of quality such as adequacy of the physical plant, credentials of the medical and nursing staff, completeness of medical records, and facilities for laboratory and radiologic diagnosis. The first survey resulted in the approval of only 89 of the 692 hospitals (12.9%) surveyed but, by 1950, 94.5% of the hospitals qualified for accreditation.

With the growth of nonsurgical specialities after World War II, the American College of Surgeons joined with the American Medical Association, the American Dental Association, the American Hospital Association, and the American College of Physicians to form the Joint Commission on Accreditation of Hospitals. Because of the increase in the variety of service institutions providing health care, the Joint Commission on Accreditation of Hospitals has recently renamed itself the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). From the one-page "Minimum Standard" of the American College of Surgeons grew the current 334-page volume entitled the *1990 Accreditation Manual for Hospitals*.[6] Although JCAHO accreditation is not mandatory, the process has a quasipublic role because accredited residency programs can only be conducted in JCAHO-approved institutions. Furthermore, the Medicare program uses the JCAHO accreditation as evidence that hospitals comply with the described standards. The new JCAHO standard requires that every hospital have a written quality assurance plan and that "there must be an objective and systematic monitoring and evaluation of the quality and appropriateness of patient care and a pursuit of opportunities to improve patient care and resolve identified problems." In its widely publicized "Agenda for Change," JCAHO is developing a new accreditation process with a uniform set of indicators of patient care quality for specific clinical and organizational units, which will be collected from each hospital and incorporated into a national data base. The pilot phase of this project was initiated with the American College of Obstetricians and Gynecologists. Obstetrics was chosen for several reasons. First, our discipline has a long history of involvement in outcome-type quality assessment activities, which are exemplified by the work of the maternal mortality and perinatal review committees. Second, the college has published a number of quality-assurance-related books over the past 15 years, and third, some believe it is easier to define aspects of care in obstetrics than in other medical specialities.[7]

In 1966, Avedis Donabedian[8] proposed that quality of health services could be monitored by three different approaches, which he termed structure, process, and outcome. Structure included items such as the number of physicians on staff and their qualifications, the nurse-patient ratio, and the equipment and number and size of facilities. These are indirect measures of outcome. The process activity comprised the evaluation of the specific steps of diagnostic and therapeutic procedures actually provided to patients. Most medical audits fall within this category. The outcome component consisted of the results achieved for the patient; it was more difficult to measure because outcome was often temporally removed from the office visit or hospitalization. However, outcome analysis or, as Codman[5] called it, "end-result assessment" is the current focus of the quality assurance requirements of all regulatory and accrediting agencies. The legal responsibility for the establishment of quality assurance programs and the quality of patient care has been assigned to hospital governing bodies.

A review of the quality assurance literature unavoidably raises the perplexing question of the meaning of quality. Although most physicians believe that differences in the quality of care can be instinctively distinguished, our perspectives, predictably, tend to be narrow because we view health as simply the absence of disease. One useful definition of quality is simply adherence to a standard. The brevity of this definition makes it attractive, but it is precisely this attribute that leaves it open to criticism. With a lofty standard, little will be acceptable, and if the standard is minimal, it will fail to discriminate among widely different levels of care.

A number of academicians have pursued the definition of quality. Avedis Donabedian[9] defined quality

as a difficult-to-identify property that medical care has in varying degrees and which, even if identified, requires translation into criteria and standards that can be used in making consistent judgments. Furthermore, he stated that judgments of quality are made not only about the medical care itself but indirectly about the persons who provide care and about the settings or systems within which care is provided. He divided the concept of management into technical care, which is the application of science and technology of medicine, and interpersonal care, which is the management of the social and psychological interactions between doctor and patient. The first represented the science of medicine; the second, the art of medicine. A third element, the amenities, was included under the interpersonal relationship category because it signified concern for patient satisfaction. Donabedian concluded by adopting the view that assessment of quality varies depending on the outcomes sought, the values placed on the outcomes, and the appropriateness of the means used to attain those outcomes. He cautioned that judgments vary depending on whether the assessment is made on behalf of individual patients or the community, whether preferences of individuals are taken into account, and whether monetary cost is included in the assessment. It is clear that for Donabedian, assessment of quality depends heavily on the perspectives of the individuals who make judgments and on the characteristics of the criteria and standards used in those judgments.

A second definition of quality is attributed to Brook and Williams,[10] who described the following formula: Quality of health care = Technical care + Art of care + Technical care × Art of care + E (random error). Technical care represents the adequacy of the diagnostic and therapeutic process, art of care relates to the psychosocial and environmental impact, the interactive term underscores the idea that technical care and art of care are not simply additive, and a random error factor signifies that some outcomes may be determined by chance.

An operational definition of quality presented by William F. Jessee[11] consists of the three following interrelated objectives: (1) optimal achievable benefits of health care for each patient, within the biologic constraints imposed by the person's illness, age, or underlying chronic diseases and within the limitations imposed by the individual's own choices in complying with health care recommendations; (2) minimal expenditure of resources necessary to achieve these benefits; and (3) avoidance of injury or additional disability that results from the provision of health care services. This definition, like that of Donabedian, links benefits, risks, and volume or costs of services. In spite of the intellectual appeal of Jessee's operational definition of quality, even he wondered whether the inclusion of an emphasis on containing costs might provide resistance and controversy in the health professions.

The words "quality assurance" evoke a negative response from many physicians. I call the following reasons, which are most often cited for this resistance, the "Ten Denouncements."

1. *The quality assurance process requires an excessive time commitment.* Even with computer-assisted data collection, the quality review process is time-consuming. It seems that the number of formal and informal meetings generated by these activities increases exponentially.

2. *No evidence exists that quality assurance programs improve quality of care.* The little evidence that exists to support the idea that programs of professional peer-review can lead to changes in medical practice comes from an evaluation of the national Professional Standards Review Organization program by the Health Care Financing Administration in 1978.[12] A number of instances were noted in which improvement in compliance with process or outcome criteria followed Professional Standards Review Organization medical audits. However, no hard data indicate that these activities improve quality. On the other hand, there is a "big-brother" mentality that expresses an attitude that when one is being watched (as in peer review), one tends to be more careful. Nevertheless, agencies insist that we demonstrate an improvement in quality for their invested dollars. This may be comparable to demanding proof from religious institutions that their tax exemptions result in the decrease in the prevalence of sin.

3. *Quality assessment has always been part of medical practice.* Quality assessment and quality assurance are not synonymous. Quality assessment means measuring the level of quality without an effort to change or improve the level of care; quality assurance includes the measurement of the level of care but implies actions to eliminate substandard performance and to improve the effectiveness of treatment. For example, our traditional educational activities of assigning responsibility, delineating scope and important aspects of care, and collecting, organizing, and evaluating data encompass most of the first seven steps of the JCAHO 10-step monitoring and evaluation process. The final three steps (taking action to resolve identified problems, assessing these actions and documenting improvement or lack of improvement, and communicating this information to parties outside our department) are activities with which physicians are uncomfortable. A frequent response from physicians when they are pressured into regulatory activities is that if they had wished

to be policemen, they would have pursued an alternate career. However, these activities, although sometimes distasteful, are implicit in the term "assurance" and are a part of the contemporary expectation of accountability.

4. *The current method of quality assurance has a punitive orientation.* Physicians are concerned with the activity of the Peer Review Organization in quality care assessment. Current federal draft regulations authorize the PRO to deny payment to a physician or hospital for services determined to be of substandard quality. Standards utilized by the local peer review organization are based on fairly general federal guidelines. Sanctions may be imposed on individual physicians by the Peer Review Organization for designated quarterly point totals; these sanctions range from educational intervention to notification of state licensing agencies and professional associations. Patients are notified of denial of payment with the language that the medical care reviewed was not acceptable under the Medicare program. The number of Peer Review Organization citations for quality will increase because of mounting pressure to increase the number of payment denials.

5. *The present system of quality assurance leads to decreased physician autonomy.* Currently in New York State, in addition to JCAHO surveys, the regulatory bodies that affect the quality of patient care include the Accreditation Council for Graduate Medical Education with its residency review surveys, the Medicare Title XVIII reviews, Medicaid reviews, and Peer Review Organization activities. In addition to the New York State Department of Health Article 28 surveys, quality is influenced by the State Board of Professional Medical Conduct, the Impaired Physicians Committee, and the New York State education law and incident reporting regulations, as well as the New York State graduate medical education regulations. These forces affect the physician who is primarily responsible for the quality of patient care.

6. *The existing process of quality assurance promotes unprofessional "cookbook" medicine.* Physicians frequently respond negatively to systematic efforts to develop standards of care because of a concern that medical practice may be reduced to inflexible rules that will prevent physicians from exercising clinical judgment and will stifle independent thinking. Rigid protocols fail to reflect the myriad possibilities that may be encountered in working with real patients.

7. *Quality assurance activities increase the cost of medical care.* Costs associated with the many programs that assure quality have not been accurately measured. It has been suggested that a standard for hospital direct costs be 1% of the operating budget of the institution. If this were a reality, more than $2.5 billion would be spent in 1990 by hospitals alone on quality assurance activities. This figure does not include the monetarily uncompensated time and effort of physicians. In addition, quality assurance committees frequently do not achieve their goals because tangential or trivial issues are addressed at considerable cost. Total costs of these activities are elusive for several reasons. First, difficulty exists in estimating what proportion of an employee's time is spent on quality assurance, except in those instances in which the employee's full-time effort is in this area. Second, since hospitals are theoretically reimbursed for quality assurance activities, finance officers are often reluctant to disclose the exact level of actual spending, and third, indirect costs are difficult to measure. Finally, cost reduction efforts generally contain quality assurance components. David Himmelstein,[13] who explored the issue of administrative waste that he termed "cost without benefit," points out that most cost containment programs "have involved . . . hiring more administrators to ensure delivery of less care . . .."

8. *Quality cannot be defined.* The concept that "quality is in the eye of the beholder" has been used by physicians as a reason that quality assurance programs have not been implemented. This quotation from Donabedian[14] is on target: "Quality is now a term too easily bandied about, and there is little hesitation in proposing that quality can be measured . . .. But this mood of almost belligerent confidence is perhaps premature, for there is much about the concept of quality that is elusive, undefined and unmeasured."

9. *Clinical uncertainties do not lend themselves to evaluation by inflexible quality assurance plans.* David Eddy[15] states that uncertainty "creeps into medical practice through every pore" and that physicians can do more to admit the existence of uncertainty, both to themselves and to their patients.[15]

10. *Fear of public disclosure and legal liability discourages optimal participation in quality assurance activities.* Two examples that breach peer-review confidentiality are the current ability of the Peer Review Organization (PRO) to publicly identify practitioners involved in Medicare or Medicaid claims that are denied for substandard care and a recent Georgia judicial decision that mandates public release of Joint Commission reports. The Health Care and Quality Improvement Act of 1986, which is known as the medical shield law, affords considerable protection to members of hospital staffs who act in good faith to monitor physicians for violations of quality of care. However, the removal of the exemption of the learned professions from antitrust laws has diminished the legal protection of the peer-review process.[16]

The existing bureaucratic programs of quality assurance will continue to exist, as will a demand for intensification of quality assurance activities. The most critical component of the current process is the setting

of standards, and for this reason the profession should be alerted to the fact that, according to Mark R. Chassin,[17] what is new in the emerging debate on methodology to establish standards is "the clear inference that standards of care are too important to be left to physicians to develop and implement." I hope that this is a minority point of view and that the public sector will continue to rely on physicians to set standards. But to which physicians will they turn?

Sociologist Eliot Freidson[18, 19] describes an increasing stratification of the medical profession that consists of an elite group of administrators, educators, and researchers and, below them, the practitioners, who are in the majority. Whereas the elite are the managers, judges, and employers, the practitioners are the managed, the judged, and the employed. This stratification appears to be more important in the segmentation of the profession because it cuts across all specialties and provides the economic, administrative, and cognitive authority over everyday practice. There has been an accelerating increase in the number of physicians who devote their efforts solely to administration. By illustration, the American College of Physicians Executives had 4898 members as of Dec. 31, 1989, and has demonstrated rapid growth. Will government and legislators turn to a cadre of administrative physicians, many of whom have little or no experience in clinical care, to assist them in specifying standards? That is possible because to regulatory agencies one doctor is much like another. But that action would definitely be unfortunate. It would be no more sensible if those agencies sought either a medical school dean who lacked clinical practice experience or a comparable full-time researcher who had never treated patients. Physicians who are involved in patient care (particularly those who are the academic and clinical leaders of our discipline) have the obligation to participate in the standard development process. The decisions in the process cannot be left to nonclinicians, whether they do or do not have medical degrees. Only clinical practitioners have the insight and experience to set these standards.

Different observers view the quality assurance process with varying goals and perspectives. Physicians often see it as interference. Consumers of health care expect quality assurance plans to assess the ability of physicians to make accurate diagnoses and institute appropriate treatments. A hospital administrator may judge a plan to be effective if it focuses on delivering the greatest number of services at the lowest possible institutional cost. The Health Care Financing Administration sees the monitoring of health care as an opportunity to improve medical practice by the collection and distribution of information on health outcomes. The Peer Review Organization measures effectiveness by achieving the greatest number of payment denials, and the New York State Department of Health is on record that these programs will weed out bad doctors and will thereby diminish malpractice. The Joint Commission would be satisfied if all hospitals met its quality assurance standards, and some economists prefer a free-market determination of quality. Certain members of congress see peer-review activities as being one road to dealing with medical malpractice.

In conclusion, consider the following: As part of the new competition, for-profit interests threaten to dominate health care. Free-standing clinics, surgicenters, emergicenters, and urgicenters are springing up all around us, and are directed by medical entrepreneurs who keep score on patient care by counting dollars. As David M. Kinzer[20] has suggested, these businesses market increased utilization and often underprice their services for those people who don't really need them in the first place. In my opinion, however, most patients, when it comes to the issue of their own health, will opt for quality if they can recognize it. The current quality assurance initiatives permit us to accept the challenge of the new competitive environment by giving us the opportunity to demonstrate to our patients that our teaching hospitals and their medical staffs do provide better quality care. If we believe this is so, we will have to prove it!

Antepartum cultures for *Ureaplasma urealyticum* are not useful in predicting pregnancy outcome

Lipscomb, RN,[h] and the Vaginal Infections and Prematurity Study Group*

Bethesda, Maryland, Oklahoma City, Oklahoma, Research Triangle Park, North Carolina, Seattle, Washington, New York, New York, New Orleans, Louisiana, and San Antonio, Texas

To test the hypothesis that genital colonization with *Ureaplasma urealyticum* would predict adverse pregnancy outcome, 4934 women from five medical centers were evaluated for vaginal colonization with *U. urealyticum* between 23 and 26 weeks' gestation and followed up to delivery. *U. urealyticum* colonization was associated with maternal age, parity, racial-ethnic group, martial status, income, education, smoking, number of sexual partners, and colonization with *Trichomonas vaginalis*, *Mycoplasma hominis*, and bacterial vaginosis. After adjustment for medical and sociodemographic factors in a multivariate analysis, there was no difference in the mean birth weight or proportion of low-birth-weight infants delivered by women who carried *U. urealyticum* and those who did not. *U. urealyticum* colonization at 23 to 26 weeks was not associated with preterm rupture of membranes, preterm labor, or preterm delivery. A positive vaginal culture for *U. urealyticum* in midgestation does not predict those women at risk for preterm labor, preterm delivery, preterm premature rupture of membranes, or delivery of a low-birth-weight infant. (AM J OBSTET GYNECOL 1991;164:728-33.)

Key words: *Ureaplasma urealyticum*, low birth weight, preterm labor, preterm birth, preterm premature rupture of membranes

Preterm birth and low birth weight are the leading causes of neonatal mortality and morbidity in the United States. The cause of most preterm births is not known, but an increasing body of evidence suggests that genital infections may contribute to preterm labor and preterm rupture of membranes.[1] It has been suggested that commonly recovered vaginal organisms such as *Ureaplasma urealyticum* may cause chorioamnionitis and preterm birth.[2] Recovery of *U. urealyticum* from the infant, the placenta, or the mother's genital tract has been associated with low birth weight[2-5] and histologic chorioamnionitis.[6, 7] However, the association of *U. urea-*

lyticum and pregnancy outcome has not been consistent, and in other studies *U. urealyticum* was not associated with adverse pregnancy outcome.[8,9] Most of the studies have had small numbers or have not controlled for potentially confounding demographic or obstetric factors, and the role of *U. urealyticum* in pregnancy outcome is controversial.

We began a multicenter study in 1984 (the Vaginal Infections and Prematurity Study) to determine the effect of genital microorganisms on pregnancy outcome. A wide variety of microorganisms were cultured from the maternal genital tract to determine their associations with preterm birth. In this report the relationship of *U. urealyticum* carriage at 23 to 26 weeks' gestation with subsequent pregnancy outcome is examined.

Material and methods

Population. The Vaginal Infections and Prematurity Study Group carried out a multicenter, multiyear study that consisted of observation of the relationships between genital colonization with aerobic and anaerobic bacteria, mycoplasmas, *Chlamydia trachomatis, Trichomonas vaginalis, Candida spp.*, demographic factors, medical and obstetric factors, and pregnancy outcome, and a randomized clinical trial of the effect of erythromycin therapy on pregnancy outcome. Women from five medical centers (Columbia Presbyterian Hospital, New York, the University of Texas Health Science Center in San Antonio, Louisiana State University, New Orleans, the University of Washington, Seattle, and the University of Oklahoma Health Sciences Center, Oklahoma City) were included in this study. Women were excluded from the study for the following reasons: insulin-dependent diabetes mellitus, current use of corticosteroids, chronic renal disease (serum creatinine level > 2.5 mg/dl), current use of digitalis, symptomatic organic heart disease, plans to deliver at a nonstudy hospital, multiple gestation, prior use of tocolytic agents during the current pregnancy, cervical cerclage, hypertension requiring medication, age < 16 years, Rh isoimmunization, or antibiotic use in the preceding 2 weeks. All women gave written informed consent approved by the respective institutional review boards of the participating centers.

Women were interviewed between 23 and 26 completed weeks' gestation. A standardized medical, obstetric, sexual, and social history and cultures of the vagina, cervix, and urine were obtained from all women on admission to the study. All women were followed up to delivery. If a woman was lost to follow-up or delivered at another hospital, an effort was made to determine the date of delivery, sex and birth weight of the infant, and any additional information about the maternal and neonatal course. Women who presented with labor or rupture of membranes before 37 weeks had vaginal and cervical cultures taken during labor, when possible. Women in labor at term during regular weekday working hours also had cultures taken.

The study included a randomized, placebo-controlled, double-masked clinical trial of erythromycin therapy for women who carried *U. urealyticum, C. trachomatis* or β-hemolytic group B streptococci. All women who carried group B streptococci or *C. trachomatis,* as well as a subset of those with *U. urealyticum,* were approached for enrollment into the clinical trial. To reduce problems with interpretation of the role of *U. urealyticum* in adverse pregnancy outcome, we excluded all women with group B streptococci or *C. trachomatis* and those women with *U. urealyticum* who were randomized into the clinical trial from these analyses. The results of the clinical trial will be presented in a separate report. Women who had >100,000 colony-forming units per milliliter isolated from urine cultures or who had *Neisseria gonorrhoeae* isolated from the cervix were treated and followed up in the observational study but were ineligible for the clinical trial. Women were not otherwise treated on the basis of the enrollment cultures.

Gestational age was determined by means of a combination of last menstrual period, early obstetric examination, and ultrasonographic evaluation, where indicated. Preterm labor was defined as spontaneous onset of regular uterine contractions before 37 weeks that led to delivery or the administration of parenteral tocolytic agents. Premature rupture of membranes was defined as spontaneous membrane rupture before the onset of regular uterine contractions, and preterm premature rupture of membranes occurred before 37 completed weeks' gestation. Low birth weight was defined as a birth weight <2500 gm, and very low birth weight was defined as a birth weight <1500 gm.

Microbiology. Specimens for *U. urealyticum* were obtained by washing the vagina with 3 ml of prereduced buffered saline solution and aspirating the wash. Shepard's A7-B agar plate was then inoculated with 0.05 ml of the wash, and the plate was streaked into four quadrants with a sterile swab premoistened with prereduced saline solution. Kenny's MES media[10] were then inoculated with 0.1 ml of the wash. Agar plates were incubated aerobically at 37° C for 3 days and observed for colony morphologic features. The broth was incubated for up to 1 week or until a pH color shift was observed. On the day of color shift the broth was subcultured or frozen at −20° C for later subculture in batch. The subculture was streaked on an agar plate and again placed in broth. Typical colony morphologic features were required from subcultured broth to confirm the presence of *U. urealyticum* when no organisms were found on the original agar plates.

Statistical methods. Data were entered onto paper forms and mailed to the Data Coordinating Center where the forms were entered into a mainframe computer. Data forms were edited and returned to the clinical centers for corrections where indicated. Data analysis was done with the Statistical Analysis System.* Continuous outcomes were analyzed with a two-sample *t* test or linear regression methods. Associations between *U. urealyticum* and dichotomous outcomes are summarized with the odds ratio, which is a good estimate of the relative risk in this circumstance. Adjustment for covariates was done by stratified analysis using the χ^2 test of Mantel and Haenszel with no continuity correction and by logistic regression analysis.

Results

From Nov. 1, 1984, until June 30, 1987, 8287 women were enrolled in the study (2600 black, 2774 Hispanic, 2675 white, and 238 women of Asian, Native American, or other racial or ethnic groups). Of these 1885 women were randomized into the clinical trial, 1359 women had group B streptococci or *C trachomatis,* and 109 of the remaining women had no evaluation for *U. urealyticum* carriage, leaving 4934 women for the analysis of *U. urealyticum* carriage and pregnancy outcome. Of these 4568 had delivery information available.

U. urealyticum was recovered from 72% of the 8287

women initially enrolled and 65.9% of the 4934 women studied in this analysis, making it the most frequently isolated organism in this study. The organism was recovered from 89% of 1511 women from the Louisiana State University, 77% of 594 women from the University of Washington, 70% of 2504 women from Columbia Presbyterian Hospital, 70% of 1244 women from the University of Texas, and 68% of 2254 women from the Oklahoma University Health Sciences Center. The associations of *U. urealyticum* carriage with behavioral and demographic factors are shown in Table I. *U. urealyticum* was recovered more commonly from black than Hispanic or white women and from primigravid women more commonly than multigravid women. The carriage rate of *U. urealyticum* declined significantly with increasing age (p for trend < 0.001), with increasing income (p for trend < 0.001), and with increasing education (p for trend < 0.001). Married women had significantly lower rates of carriage than either unmarried or previously married women. We isolated *U. urealyticum* significantly more often from women who smoked during or in the 3 months before pregnancy than in nonsmokers but found no difference between those who drank alcohol and those who did not. *U. urealyticum* carriage was strongly associated with increasing numbers of sexual partners in the last year (p for trend < 0.001), as well as with increasing numbers of sexual partners during the pregnancy or in the woman's lifetime (data not shown).

U. urealyticum carriage was significantly associated with recovery of *T. vaginalis* and *N. gonorrhoeae* but not *Candida albicans* (Table II). *U. urealyticum* was also associated with bacteria vaginosis (on the basis of Gram's stain diagnosis), and the organisms often isolated in association with this syndrome (*Gardnerella vaginalis, Bacteroides spp., Mycoplasma hominis,* anaerobic lactobacilli, and peptococci).

Pregnancy outcomes. Seven percent (322/4453) of the infants born to women in this analysis weighed <2500 gm and 1.4% (64/4453) weighed <1500 gm. The mean birth weight of all infants in this analysis was 3282 gm. Eleven percent (511/4520) were delivered before 37 weeks, 10.4% (466/4529) had preterm labor, and 3.1% (141/4529) had preterm premature rupture of membranes.

Women who carried *U. urealyticum* were slightly more likely to be delivered of a low-birth-weight infant than were those who did not (7.9% vs 6.1%, $p = 0.02$, Table III). Women who carried *U. urealyticum* were also more likely to be delivered of a very-low-birth-weight-infant (1.6% vs 0.9%, $p = 0.04$, Table III). To determine if *U. urealyticum* carriage was an independent risk factor for low birth weight, we performed a stepwise multiple logistic regression. After adjusting for ethnicity, smoking, parity, and carriage of *T. vaginalis,* we found that *U. urealyticum* was not significantly associated with low birth weight (Table IV) or very low birth weight. Addition of other potential confounders to the model had no effect.

Pos., Positive; *neg.*, negative.

Women who carried *U. urealyticum* were delivered of infants with a mean birth weight of 3276 gm (SD, 583 gm) and those who did not had infants with a mean birth weight of 3325 gm (SD, 559 gm; $p < 0.01$). After adjustment for parity, ethnicity, and smoking during pregnancy, the adjusted mean difference attributable to *U. urealyticum* was 22 gm (F 1.37, $p > 0.2$), and after adjustment for those factors plus marital status, income, ethanol use, marijuana use, and isolation of *T. vaginalis, M. hominis,* or *N. gonorrhoeae,* the adjusted mean difference attributable to *U. urealyticum* was 1 gm (F 0.00, $p > 0.95$).

There was no significant difference in the rates of preterm delivery, preterm labor, or preterm premature rupture of membranes between women who had positive cultures for *U. urealyticum* and those who did not (Table III). Stratifying these rates by race or ethnic

Table III. Pregnancy outcomes as related to *U. urealyticum* carriage at 23 to 26 weeks' gestation

Outcome	*U. urealyticum–positive*	*U. urealyticum–negative*	*p Value*
Labor <37 wk	10.4% (306/2940)	10.2% (160/1564)	0.9

Labor before 37 wk	1.0	0.8-1.2	1.0	0.8-1.2
Preterm premature rupture of membranes before 37 wk	0.9	0.6-1.3	0.9	0.6-1.2

group, site, or other variables did not alter these results. Stepwise multiple logistic regressions examining the relationship of *U. urealyticum* carriage with preterm labor, preterm delivery, and preterm premature rupture of membranes showed that colonization with *U. urealyticum* in midgestation was not a significant predictor of preterm birth, preterm delivery, or preterm premature rupture of membranes after adjustment for potential confounders (Table IV).

We performed similar analyses of *U. urealyticum* carriage and the association between *U. urealyticum* colonization and outcome, including the women who were randomized in the clinical trial. No important differences were noted in the risk factors for *U. urealyticum* isolation or in the association between *U. urealyticum* isolation and pregnancy outcome (data not shown).

Comment

This study agrees with previous studies, which have failed to show an association between genital colonization with *U. urealyticum* and pregnancy outcome.[8, 9, 11, 12] Previous reports linking *U. urealyticum* to pregnancy outcome have shown an association between isolation of the organism from the placenta,[5, 6, 13, 14] the newborn infant,[7, 10] or genital cultures taken at delivery[8] and preterm birth or low birth weight. Preterm labor has been associated with other genital microorganisms such as group B streptococci,[15] *C. trachomatis*,[16] and bacteria[17, 18] and with bacterial vaginosis.[19] It is therefore important to control for the presence of other organisms when associations with pregnancy outcome are studied. We found an association between isolation of *U. urealyticum* and other genital microorganisms and an association between *U. urealyticum* and sociodemographic factors previously reported to be associated with low birth weight.[20] Although we found a weak association between antepartum colonization with *U. urealyticum* and low birth weight on univariate analysis, this association was not significant after we controlled for these sociodemographic factors and other microorganisms. Although we cannot exclude a role for *U. urealyticum* in low birth weight, our analysis indicates that the association between *U. urealyticum* carriage in the lower genital tract and low birth weight is weak and of minimal clinical significance when compared with these other factors.

The analyses presented here exclude women who were in the randomized clinical trial of erythromycin therapy, because the trial results will be published in a separate report. Our results could have been influenced by a selection bias if women in the trial with *U. urealyticum* had a different risk for adverse outcome than those who were not in the trial. Consequently we performed similar analyses that included women in the trial, and our conclusions were the same as those we have reported. It is possible that women with *U. urealyticum* and either group B streptococci or *C. trachomatis* were at higher risk. We chose to exclude these women to clearly see an effect of *U. urealyticum* on pregnancy outcome.

The results of this study indicate that antepartum genital cultures for *U. urealyticum* are not of value in predicting pregnancy outcome. Women who carried *U. urealyticum* were no more likely to have preterm premature rupture of membranes, preterm labor, or preterm delivery than those who did not. After adjustment for sociodemographic factors, *U. urealyticum* isolation was not significantly associated with low birth weight.

Routine antepartum cultures for *U. urealyticum* are not justified to predict women at risk for adverse pregnancy outcome.

Other members of the Vaginal Infections and Prematurity Study Group are as follows: Sumner J. Yaffe, MD, Charlotte S. Catz, MD, George G. Rhoads, MD, MPH (now at the University of Medicine and Dentistry of New Jersey), Donald McNellis, MD, Mark A. Klebanoff, MD, MPH, Howard J. Hoffman, MA, and Heinz W. Berendes, MD, MHS, from the National Institute of Child Health and Human Development; Robert Edelman, MD (now at the University of Maryland), Richard A. Kaslow, MD, MPH, Mary Frances Cotch, PhD, and George F. Reed, PhD, from the National Institute of Allergy and Infectious Disease; Arlene Meier, RN, from the University of Oklahoma; Luann Wenthold, RNC, from the Louisiana State University; and W. Kenneth Poole, PhD, and Betty K. Hastings from the Research Triangle Institute.

Ureaplasma urealyticum has been associated with low birth weight and histologic chorioamnionitis and it is a frequent isolate from the chorioamnion of patients who are delivered prematurely. In prior clinical trials using antibiotics active against *U. urealyticum*, antibiotic treatment was associated with reduced prematurity and increased mean birth weight. In this multicenter, randomized, double-blind clinical trial, pregnant women with *U. urealyticum* were treated with 333 mg of erythromycin base or placebo three times daily, starting between 26 and 30 weeks' gestation and continuing through 35 completed weeks of pregnancy. Women with urinary tract infection or *Neisseria gonorrhoeae* infection were excluded from the trial, and women with *Chlamydia trachomatis* or group B streptococci were excluded from these analyses. Erythromycin did not eliminate *U. urealyticum* from the lower genital tract. There were no significant differences between erythromycin- and placebo-treated women in infant birth weight or gestational age at delivery, in frequency of premature rupture of membranes, or in neonatal outcome. (Am J Obstet Gynecol 1991;164:734-42.)

Key words: *Ureaplasma urealyticum*, erythromycin, low birth weight, preterm birth, preterm premature rupture of membranes, clinical trial

An association between low birth weight and *Ureaplasma urealyticum* was first noted in a report of lower mean birth weight among infants with *U. urealyticum* in the nose and throat when compared with infants without the organism.[1] In these early studies an association was also found between birth weight and *U. urealyticum* recovery from a maternal genital culture[2] and between histologic chorioamnionitis and the recovery of the organism from the mother or infant.[3] More recently, histologic chorioamnionitis and poor pregnancy outcome also have been associated with recovery of *U. urealyticum* between the chorion and amnion.[4-6]

A role of *U. urealyticum* in prematurity has also been implied from two antibiotic trials. In a study conducted from 1963 to 1965, nonbacteriuric pregnant women receiving tetracycline were delivered of fewer premature live-born infants than placebo-treated women.[7] Subsequently erythromycin or placebo was administered to pregnant women with either *U. urealyticum* or *Mycoplasma hominis*.[8] Among women who were treated in the third trimester and who were considered to have successfully completed 6 weeks of therapy, patients who received erythromycin were delivered of infants with significantly higher birth weight as compared with those who received placebo.

However, other data suggesting that *U. urealyticum* caused prematurity, premature rupture of the membranes, or low birth weight have not been as convincing. In a recent large prospective study, *U. urealyticum* was

not related to prematurity.[9] The recovery of *U. urealyticum* from amniotic fluid of women in premature labor was not associated with premature delivery, whereas recovery of bacteria from amniotic fluid was highly associated with premature delivery within a day.[10]

This randomized, double-blind, controlled trial was designed to assess the effectiveness of erythromycin in preventing prematurity among women with *U. urealyticum*. Pregnant women had cultures taken for *U. urealyticum* and other known genital pathogens, except for viruses.

Material and methods

Study design. As part of a multicenter Vaginal Infection and Prematurity Study, pregnant women were enrolled in five antepartum clinics (Columbia Univeristy, New York; Louisiana State University, New Orleans; University of Oklahoma, Oklahoma City; University of Texas Health Science Center, San Antonio; and University of Washington, Seattle). Representatives from each of the centers and from Research Triangle Institute and the National Institutes of Health agreed to a uniform protocol, including questionnaire and laboratory methods. Women seeking prenatal care between the twenty-third and twenty-sixth completed week of pregnancy were screened for eligibility to enter the observational phase of the study. Women were eligible if they were ≥16 years old, were free of medical conditions (hypertension, severe renal or cardiac disease requiring medication, diabetes requiring insulin) and obstetric conditions (erythroblastosis, multiple gestation, cervical cerclage) related to premature delivery, and were not taking selected medications (antibiotics within the previous 2 weeks or current tocolytic or steroid use). Patients who agreed to participate signed a consent form approved by the human subjects protection committee at each institution. Research personnel obtained demographic, obstetric, sexual, contraceptive, and drug use history on standardized coded forms; performed a standardized physical and pelvic examination; and collected urinary-genital cultures in a standard manner.

Patients whose screening cultures contained *Neisseria gonorrhoeae* or $\geq 10^5$ microorganisms per milliliter in a urine culture were treated and were ineligible for the randomized clinical trial. Other criteria for exclusion from the trial included allergy to erythromycin, use of antibiotics since the screening examination and cultures, current use of theophylline (because it reacts with erythromycin), and a history of jaundice or liver disease within the past 3 years. Women carrying *U. urealyticum*, group B streptococci, and *Chlamydia trachomatis* were considered for randomization into the trial. However, patients with *C. trachomatis* or group B streptococci (with or without *U. urealyticum*) have been removed from these analyses. Results of the trial for patients with group B streptococci and *C. trachomatis* will be reported separately.

Patients who had *U. urealyticum*, group B streptococci, or *C. trachomatis* recovered at the screening visit were invited by telephone or in person to participate. Women who agreed to participate in the trial signed a second consent form and entered a 1-week placebo run-in that has been described in further detail elsewhere.[11] Patients who took less than two thirds of the pills or did not return to the clinic were dropped from consideration for the randomized trial.

Women who successfully completed the placebo run-in, still agreed to participate, had none of the exclusion criteria, and were at <30 weeks' gestation were randomized into the double-blind, placebo-controlled trial. Numbers corresponding to packets of either erythromycin or placebo were individually assigned to patients by Research Triangle Institute, using a balanced randomization scheme, at the time of a telephone call for each enrollee. The randomization was done by computer according to a permuted-block procedure with random block sizes (randomly selected between two, four, and six). The randomization was done within strata defined by clinical centers and the seven combinations of the three microorganisms under study. Patients received either erythromycin base, 333 mg, or identical-appearing placebo tablets to be taken three times daily from blister packs containing 21 pills. The erythromycin and placebo were kindly supplied by The Upjohn Company, Kalamazoo, Mich.* Patients were given the telephone number of study personnel and encouraged to report any side effects or difficulties in compliance. The women were elevated at each regular antenatal visit, at which time compliance (by pill count) and side effects were discussed with the research nurse using a standardized questionnaire; used blister packs were collected; and additional medication was supplied. Women were instructed to take the study medication for 10 weeks or until the end of the thirty-fifth week of pregnancy, whichever came first.

Repeat genital cultures were obtained between 31 and 34 weeks' gestation from the first 100 women enrolled into the clinical trial at each center. In addition, a randomly selected sample of 12% of patients originally enrolled in the observational study were asked to return for a repeat of all genital cultures, including

*The use of this medication does not represent an endorsement by the National Institutes of Health or the U.S. Public Health Service.

U. urealyticum (6% at 31 to 33 weeks' gestation and 6% at 34 to 36 weeks' gestation). Genital cultures also were obtained from women admitted for preterm pregnancy complications at <37 weeks' gestation (premature labor, rupture of membranes, etc.) and from patients admitted to the hospital in term labor during daytime hours of weekdays. Patients admitted to the hospital for pregnancy complications or in labor had pertinent pregnancy, labor, and delivery information collected on standardized forms.

Genital examination and collection of urogenital specimens. A clean, unlubricated speculum was placed into the vagina; the appearance of the vaginal discharge and pH were noted. Sterile cotton swabs were used to obtain vaginal material from the posterior vaginal fornix for the culture of *Trichomonas vaginalis* and group B streptococci and for vaginal Gram's stain. Prereduced sterile phosphate-buffered saline solution (3 ml) was placed into the vagina, and vaginal discharge was mixed with the solution by swabbing discharge from the lateral vaginal walls into the solution. The material was then removed with a needle and syringe and injected into an air-free tube for transport to the microbiology laboratory. All cultures were placed on media within 6 hours of collection.

Vaginal discharge was wiped from the cervical portio, and the appearance of endocervical mucus and the cervix was noted. Sterile cotton swabs were used to obtain endocervical material for Gram's stain and *N. gonorrhoeae* and group B streptococcal culture, and a sterile Dacron swab was used to obtain a *C. trachomatis* culture. Midstream urine cultures were collected after women had washed the perineal area with a cleansing solution placed on sterile gauze. Urine was plated onto MacConkey's media with a standard calibrated loop.

Culture methods. Vaginal wash (0.05 ml) was placed on solid mycoplasma media[12] and into separate liquid media for the recovery of *U. urealyticum* and *M. hominis*.[13] Soy extract was kindly supplied by George Kenny, University of Washington from lots that supported adequate mycoplasma growth. Both of the genital mycoplasmas were identified by typical morphologic features on solid media. Liquid media were examined daily for 7 days, and a color change indicating growth was confirmed by identifying typical colonies on subculture onto solid media.

Definitions. Gestational age was estimated from the last menstrual period, subject to correction from pregnancy test, first pelvic examination, fetal heart tone, and available ultrasonographic information. Premature labor was defined as spontaneous onset of regular uterine contractions before 37 weeks that led to delivery or the administration of parenteral tocolytic agents. Premature rupture of membranes was defined as rupture of membranes at any time before the onset of regular uterine contractions.

Statistical analysis. The coded questionnaires on history, physical examination, and laboratory results were sent to Research Triangle Institute, where the data were keyed, verified, and edited. The data were analyzed by means of analysis of variance for continuous variables and contingency table methods for categoric variables. Also χ^2 tests for association were used to test for differences in the distribution of categoric variables between treatment groups. When treatment group comparisons were adjusted for a single categoric factor, a Mantel-Haenszel test was done. However, the p values given in the tables are for tests of the differences between the two treatment groups for patients in specific strata; they are not based on Mantel-Haenszel statistics. Further analysis of the data was done with a logistic regression model, which included all the stratification factors used in Table IV except compliance. The efficacy of the clinical trial was periodically monitored by conditional power techniques. These procedures permit the estimation of the probability of observing a statistically significant difference at the end of the trial, given the information accumulated at some time point before the trial's termination date. The statistical computations were done with SAS procedures.*

Results

Between Nov. 1, 1984, and June 30, 1987, 8287 pregnant women were enrolled into the observational phase. *U. urealyticum* was recovered from 5998 women (72%), including 4302 women who had *U. urealyticum* recovered but did not have group B streptococci, *C. trachomatis*, *N. gonorrhoeae*, or a urinary tract infection. Of these 4302 patients with *U. urealyticum* alone, 245 women were ineligible for the clinical trial and 2113 women were not, or could not be, contacted for enrollment into the clinical trial. Of the remaining 1944 women who were both eligible and contacted for the clinical trial, 69 women (4%) decided against enrollment, 436 (22%) did not comply with the placebo run-in, and 258 (13%) were not enrolled into the run-in, mainly because of appointment failures. The remaining 1181 (61%) of 1944 women were randomized into the double-blind trial; 605 women received erythromycin and 576 women received placebo (Table I). Repeated attempts were made to obtain data on patients who were delivered elsewhere or who were lost to follow-up; complete

data were obtained for 95% of patients enrolled into the trial.

Enrollment in the *U. urealyticum* portion of the clinical trial was terminated in July 1987 on the recommendation of the Data and Safety Monitoring Committee. The committee's decision was based on conditional power calculations, which revealed a very low probability of observing a statistically significant difference in outcomes between the treatment groups in patients with *U. urealyticum* if the trial continued to its planned termination date of March 1989. Also, there was a trend toward increased gastrointestinal side effects in the erythromycin group.

The two randomized groups were compared with respect to several demographic, behavioral, and obstetric characteristics, as shown in Table I. There were no major differences in mean age or demographic, behavioral, or obstetric characteristics between women assigned to erythromycin and those assigned to placebo. The following factors also were not found to differ in patients who received erythromycin and placebo: frequency of smoking, smoking before or during pregnancy; alcoholic drinks in first or last 3 months of pregnancy or before pregnancy; living arrangement; highest year of education; medical payment; working during pregnancy; number of sexual partners during pregnancy, in last year, or during lifetime; frequency of intercourse; prior genital infection or prior kidney infection; cone biopsy; difficulty becoming pregnant; planned pregnancy; hospitalization during pregnancy; mean height or mean weight; general health; illicit drug use; prior spontaneous or induced abortions, stillbirth,

ectopic pregnancy, or low-birth-weight infants; and color, consistency, or amount of vaginal discharge or color of cervical discharge.

At initial screening examination, conducted between 23 and 26 completed weeks of pregnancy, *U. urealyticum* was recovered from 89% of 1511 patients at Louisiana State University, 77% of 594 patients at University of Washington, 70% of 2504 patients at Columbia University, 70% of 1244 patients at University of Texas, and 68% of 2254 patients at University of Oklahoma. *U. urealyticum* isolation after approximately 4 weeks of either erythromycin or placebo treatment (at 31 to 36 weeks' gestation) is listed for each of the five centers in Table II. The differences in the recovery of *U. urealyticum* between the erythromycin and placebo patients were not statistically significant at the $p = 0.05$ level, with or without adjustment for center. Among patients who were delivered before 37 weeks' gestation, *U. urealyticum* was recovered from 18 (86%) of 21 patients who received erythromycin and 15 (94%) of 16 patients who received placebo. Among those who were delivered at or beyond 37 weeks of pregnancy, *U. urealyticum* was recovered from 102 (76%) of 135 patients who received erythromycin and 96 (78%) of 123 patients who received placebo. The recovery of *U. urealyticum* at delivery did not differ significantly between the erythromycin and placebo groups or between women with or without rupture of membranes before culture. The semiquantitative concentration of *U. urealyticum* in the lower genital tract also was not appreciably changed after either erythromycin or placebo therapy.*

A comparison of selected outcome variables among patients who received erythromycin and placebo are shown in Table III. Of all patients entered into the double-blind clinical trial, the mean birth weight of infants was similar in the erythromycin and placebo groups. The distribution of birth weight by standard weight groups and the obstetric estimate of gestational age at delivery were also similar between the erythromycin and placebo groups. There were similar proportions of patients in the two groups with premature rupture of the membranes, premature labor before 37 weeks' gestation, Apgar scores ≤5, stillbirths, and neonatal deaths.

The frequencies of adverse outcomes were analyzed, with separate adjustment for each of the variables included in Table IV (except for compliance) by means of the Mantel-Haenszel procedure and simultaneously with a logistic regression model. In none of these analyses was the difference between the placebo group and erythromycin group statistically significant at the $p = 0.05$ level.

Subset analyses were undertaken to assess whether a particular subgroup of individuals could have received benefit from erythromycin. The effects of erythromycin versus placebo on birth weight <2500 gm was

Other variables tested and not found to be associated with birth weight in the clinical trial include: ethnicity, smoking, alcohol use, marijuana or cocaine use, sexual acitivity or bleeding during pregnancy, and bacterial vaginosis, *T. vaginalis*, *Lactobacillus*, *M. hominis*, or any *Bacteroides spp.* at the first enrollment visit.

*Variables that were signficantly different between the randomized groups. Other variables that differed significantly between the randomized groups but among whom erythromycin therapy did not influence birth weight included type of usual health care and number of prior live-born infants.

†Miscarriage, stillbirth, or infant birth <2500 gm with last pregnancy.

compared for those women considered at high risk for prematurity and for those women with the four characteristics that differed significantly between the erythromycin and placebo groups in this study (Table IV). There were no statistically significant or clinically significant differences between the erythromycin (8%) and placebo (6%) groups in the proportion of infants with birth weight <2500 gm, among patients in any of the subgroups presented in detail in the table, or in any of the groups listed at the bottom of Table IV.

The mean birth weight was significantly increased for erythromycin compared with placebo only for the group with a clinical amniotic fluid infection. The mean birth weight for those with a clinical amniotic fluid infection was 3700 gm for the erythromycin group and 3235 gm for the placebo group ($p = 0.005$).

The effect of erythromycin versus placebo was also compared for delivery before 37 weeks and for premature rupture of the membranes, among the variables listed in Table IV (data not shown). There was no in-

Table V. Comparisons of the rates of compliance, withdrawal, and maternal side effects between the erythromycin-treated group and the placebo-treated group

	Erythromycin (N = 605)	*Placebo (N = 576)*	*p Value*
No. withdrew	82 (14%)	53 (9%)	0.02
Patient compliance	*n = 577*	*n = 543*	
Mean days on ≥2 pills	36.5	38.1	0.03
Mean days on 3 pills	30.7	32.6	0.05
Mean No. of days on pills	38.2	39.7	0.06
Maternal side effects	*n = 586*	*n = 548*	
Appetite loss	91 (16%)	79 (14%)	NS
Nausea	194 (33%)	142 (26%)	0.01
Vomiting	102 (17%)	76 (14%)	NS
Diarrhea	94 (16%)	64 (12%)	0.03
Vaginal or rectal itching	55 (9%)	48 (9%)	NS
Any of above	256 (45%)	218 (40%)	0.06
Maternal bilirubin >1.0	0/179	2/201 (1%)	NS
Serum glutamate pyruvate transaminase more than twice normal	4/178 (2%)	8/196 (4%)	NS

fluence of erythromycin on delivery before 37 weeks' gestation or on premature rupture of membranes within any of these groups.

More women assigned to erythromycin (14%) than to placebo (9%) withdrew from the study ($p = 0.02$, Table V). The mean number of days patients took at least two pills daily or took all three pills daily and the mean number of days pills were taken were slightly higher in the placebo group than in the erythromycin group ($p < 0.05$ for each analysis). Nausea and diarrhea occurred more frequently in patients who received erythromycin than in those receiving placebo ($p < 0.05$ for each analysis). However, most of the side effects were mild and did not appreciably influence continuation in the study.

Comment

In this multicenter, randomized, double-blind trial there was no appreciable effect of erythromycin therapy on any of the pregnancy outcomes considered here, including birth weight, gestational age at delivery, premature rupture of the membranes, neonatal death, or other measures of neonatal outcome. The results of this study differ from the results of two prior trials of antibiotic treatment to prevent prematurity.[7, 8] In the first trial[7] nonbacteriuric women receiving tetracycline gave birth to significantly fewer premature live-born infants (5%) than women who received placebo (15%). The antibiotic was given for 6 weeks, starting before the thirty-second week of pregnancy. The mean gestational age at delivery in both the antibiotic and placebo group was >38 weeks. It was not possible to associate the effect of the antibiotic with any particular pathogen because genital cultures were not obtained. In the second trial[8] women with genital mycoplasmas (>90% had *U. urealyticum*) were treated with erythromycin (the stearate or estolate form) or placebo starting between the twenty-second and thirty-second week of pregnancy with dose (250 mg four times daily) and duration (6 weeks) similar to those of the present study. The 143 gm increase in birth weight ($p < 0.047$ with a one-tailed test) was evident only among compliant women who completed a 6-week regimen of antibiotic starting in the third trimester, but there was no overall reduction of prematurity among women who had received erythromycin in that study.[8]

There is a major difference in the design of this study compared with the two prior studies. In this analysis women with *C. trachomatis*, group B streptococci, *N. gonorrhoeae*, and urinary tract infections have been excluded. All of these infections have been related to prematurity,[7, 9, 14, 15] and it is possible that antibiotic therapy eliminated them, or other tetracycline-sensitive or erythromycin-sensitive organisms, rather than *U. urealyticum*, in the two prior antibiotic studies.[7, 8]

Although we found no effect of treatment, it is still possible that antibiotic therapy is of benefit for the prevention of prematurity, but treatment may need to be started earlier in pregnancy. The proportion of patients with evidence of upper genital tract infection (of amniotic fluid or chorioamnion) is not constant throughout pregnancy. The prevalence of histologic chorioamnionitis[4, 6, 16] and of microorganisms recovered from the chorioamnioin[6] is highest in the second trimester, intermediate in the early third trimester, and lowest at term. Histologic chorioamnionitis has been related to the recovery of organisms, including *U. urealyticum*, from the space between the chorion and amnion.[4-6] The majority of women in the present study were treated starting at or beyond the twenty-ninth week of gestation, and it is possible that treatment earlier in pregnancy would have been more effective in preventing

infection-related prematurity than therapy begun at this time in pregnancy. Since only 1% of women are delivered of neonates weighing ≤1500 gm at birth (approximately 32 weeks' gestation), a very large number of women would have had to be treated with antibiotics to demonstrate a measurable impact on prematurity if the major preventive effect of antibiotics occurs before 32 weeks' gestation.

A subset of women could be uniquely susceptible to the effect of *U. urealyticum* and hence to prematurity. Potentially, these women could include those with particularly pathogenic strains of *U. urealyticum*, with newly acquired infection or without antibody protection against the microorganism. *C. trachomatis* has been associated with premature delivery and premature rupture of membranes among women with immunoglobulin M, presumably as a result of a newly acquired infection, but not among women with immunoglobulin G antibody, presumably representing chronic carriage of the microorganism.[9] There is evidence that women with a four fold rise in antibody titer to *U. urealyticum* may have an increased risk of premature delivery.[17]

U. urealyticum was not eliminated from the lower genital tract of women receiving erythromycin, either in this trial or in the previous trial.[8] Thus the presence of the microorganisim possibly could have still influenced the pregnancy outcome of both the erythromycin and placebo groups. *U. urealyticum* is susceptible in vitro to erythromycin and tetracycline,[18] but neither antibiotic has effectively eliminated *U. urealyticum* from the lower female genital tract, probably because of the effect of the acidic vaginal pH on the antibiotic.[18] However, lower genital tract *U. urealyticum* would be expected to produce its effect on pregnancy only if it ascended into the upper genital tract. Although tissue concentrations of erythromycin are typically low, erythromycin levels would be expected to be sufficient to inhibit the spread of susceptible microorganisms into upper genital tract sites. Other oral antibiotics that effectively inhibit *U. urealyticum* have toxicity in pregnancy.

The absence of an effect of erythromycin on either *U. urealyticum* colonization or pregnancy outcome might also suggest that some patients did not take the medication. Serum erythromycin levels were not obtained to directly address this issue. Evidence against this position occurs for women in this trial who were colonized with group B streptococci or *C. trachomatis*. In a preliminary report to the Data and Safety Monitoring Committee, erythromycin in the same dose and duration effectively eliminated *C. trachomatis* and group B streptococci. Although gastrointestinal intolerance is a major problem with many erythromycin preparations, the preparation used here was well tolerated.

The absence of an antibiotic effect cannot be explained by a chance failure of the scheme to randomly assign women to erythromycin and placebo groups with different risks for prematurity. The two randomized groups were comparable for characteristics considered to be potential risk factors for prematurity, as well as for numerous other factors noted. There was little chance that the results could be explained by a disproportionate number of patients with other infections previously associated with prematurity. These infections were either excluded from the study (urinary tract infection, *N. gonorrhoeae*), excluded from the analysis (*C. trachomatis*, group B streptococci), or present at similar proportions in the erythromycin and placebo groups (bacterial vaginosis,[19] *T. vaginalis*[20]). The absence of an effect could not be explained by brevity of the antibiotic course, noncompliance, or loss to follow-up, since the mean duration of therapy was 36 days, >80% of the patients took an average of more than two pills per day, and fewer than 15% of randomized patients withdrew from the trial.

We conclude that erythromycin therapy is not justified for the treatment of *U. urealyticum* in the lower genital tract to prevent prematurity.

Evaluation of an aneurysm of the vein of Galen in utero by pulsed and color Doppler ultrasonography

Junji Ishimatsu, MD, Osamu Yoshimura, MD, Masahiro Tetsuou, MD, and Teiji Hamada, MD

Fukuoka-Ken, Japan

Pulsed and color Doppler ultrasonographic diagnosis of an anuerysm in one of Galen's veins was achieved prenatally on the basis of the findings of turbulence blood flow in the cerebral cystic lesion and low vascular resistance in the internal carotid artery, the posterior communicating artery, and the posterior cerebral artery. (AM J OBSTET GYNECOL 1991;164:743-4.)

Key words: Prenatal diagnosis, aneurysm of the vein of Galen, pulsed and color Doppler ultrasound, fetal hemodynamics

Described in this article is one case of aneurysm of a Galen's vein in utero, and to our knowledge this is the first report that demonstrates a complete mapping of the fetal intracranial circulation with this phenomenon in conjunction with cardiovascular hemodynamics as evaluated by pulsed and color Doppler ultrasonography.

Case report

A 29-year-old woman, gravida 1, para 1, was referred to Kurume University Hospital at 37 weeks and 1 day of gestation for evaluation of a round intracranial lesion. Color Doppler ultrasonography (Aloka SSD-680, Aloka Co. Ltd., Tokyo) with 3.5 MHz transducer revealed the presence of well-defined cerebral cystic space that measured 29 × 30 × 37 mm and was associated with blood flow within the lesion (Fig. 1) and within the dilated posterior cerebral artery and the straight sinus (7 mm). The blood continued to flow into the cystic lesion through both of the feeding posterior cerebral arteries and to flow into the straight sinus through the cystic lesion. The cystic structure was contiguous to the left lateral ventricle, just superior to the thalamus. The blood flow velocity waveforms of the vessels in the fetal cranium, the abdominal aorta, and the umbilical artery were measured by pulsed Doppler ultrasonography. The resistance index (i.e., peak systolic velocity minus end-diastolic velocity divided by peak systolic velocity) values were significantly elevated in the umbilical artery (0.807), the abdominal aorta (0.962), the anterior cerebral artery (0.850), and the middle cerebral artery (0.886). In contrast, the values were relatively low in the internal carotid artery (0.625) and the posterior communicating artery (0.621), and values were extremely reduced in the posterior cerebral artery (0.356) (Fig. 2). The peak systolic blood flow velocity at the entrance of the cystic lesion was markedly increased (>220 cm/sec) and the resistance index value was 0.318. There was no difference of resistance index value in arteries of bilateral hemispheres. Marked turbulence flow was seen within the cystic lesion and the straight sinus. No structual abnormalities of the fetal heart were seen. The total cardiac dimension of 46 mm exceeded the normal range. Fractional shortenings of the right ventricle (23%) and the left ventricle (33%), ratios between the maximal velocity of early passive ventricular filling and the maximal velocity of active ventricular filling during atrial contraction over the tricuspid valve (0.75) and the mitral valve (0.78), the mean velocities over the tricuspid valve (37 cm/sec) and the mitral valve (36 cm/sec), and the maximum blood flow velocities in the ascending aorta (110 cm/sec) and the pulmonary artery (91 cm/sec) were within the normal range. Retrograde diastolic flow was observed in the aortic arch. Mitral and tricuspid regurgitations were not observed. There were no pericardiac or pleural effusions, ascites, or skin edema. The intracranial abnormal blood flows, the retrograde diastolic flow in aortic arch, and the enlargement of the fetal heart suggested the vascular "steal" phenomenon of the aneurysm of the Galen's vein both of the posterior cerebral arteries. A female infant who weighed 3040 gm was delivered by cesarean section at 38 weeks and 4 days of gestation. The embolizations in both of the feeding posterior cerebral arteries via the internal carotid arteries were successfully achieved on the second and eighth days of life. The infant was discharged on thirty-eighth postnatal day and had not manifested either neurologic or cardiac involvement.

Comment

Prenatal diagnosis of this phenomenon has rarely been done. Only a few cases were reported regarding the Doppler ultrasonographic examination of the fetus

with this malformation.[1,2] In the present case, complete mapping of the intracranial vessels by pulsed Doppler ultrasonography permitted us to achieve the precise prenatal diagnosis and the subsequent treatment for favorable prognosis of the infant.

We believe that the pulsed and color Doppler ultrasonography is the most useful noninvasive method for the identification of vascular abnormalities and the evaluation of hemodynamics in the fetus.

Epidermal growth factor receptor expression in normal ovarian epithelium and ovarian cancer

II. Relationship between receptor expression and response to epidermal growth factor

Gustavo C. Rodriguez, MD,[a] Andrew Berchuck, MD,[a] Regina S. Whitaker, BS,[a] David Schlossman, MD, PhD,[b] Daniel L. Clarke-Pearson, MD,[a] and Robert C. Bast, Jr., MD[b, c]

Durham, North Carolina

Previously we have shown that epidermal growth factor acts as a mitogen for some, but not all, ovarian cancer cells in culture. In this study we examined the effect of epidermal growth factor on proliferation of normal human ovarian epithelial cells in monolayer culture. We found that epidermal growth factor stimulated twofold to fourfold increases in proliferation in epithelial cells from each of five normal ovaries ($p < 0.01$). In addition, Scatchard analysis of binding of epidermal growth factor tagged with iodine 125 indicated the presence of high-affinity receptors in all of the ovarian epithelial cells and ovarian cancer cell lines. The number and affinity of receptors was similar in the normal epithelium and cancer cell lines, and there was no relationship between epidermal growth factor receptor number and responsiveness to epidermal growth factor. We conclude that human ovarian epithelial cells normally express epidermal growth factor receptors and that epidermal growth factor acts as a mitogen for these cells. Although the mitogenic response to epidermal growth factor often is attenuated in ovarian cancer cell lines, loss of responsiveness to epidermal growth factor does not appear to be due to decreased receptor expression.
(Am J Obstet Gynecol 1991;164:745-50.)

Key words: Epidermal growth factor receptor, epidermal growth factor, ovarian cancer

Epidermal growth factor is a 6045 d polypeptide that acts as a mitogen for a wide variety of cells in vitro. The epidermal growth factor receptor is a 170,000 d transmembrane glycoprotein that includes a cysteine-rich, extracellular ligand-binding domain, a short hydrophobic membrane-spanning region, and an intracellular tyrosine kinase domain.[1] In addition to activation of the receptor tyrosine kinase, binding of epidermal growth factor to its receptor stimulates several other biochemical events.[2] Although these "second messengers" are thought to play a role in transmission of the mitogenic signal to the nucleus, our understanding of these events remains incomplete.

The epidermal growth factor receptor is widely expressed in normal human tissues, including both epithelial and mesenchymal cells, and it is thought that epidermal growth factor and its receptor are involved in processes of normal cellular growth and differentiation in vivo. In addition, various abnormalities of the epidermal growth factor receptor and its ligands have been described in human cancers. For example, in squamous cancers it has been noted that epidermal growth factor receptor expression often is increased relative to normal squamous cells.[3] In contrast, it has been reported that only a fraction of breast cancers express epidermal growth factor receptor. In breast cancer, epidermal growth factor receptor expression has correlated inversely with estrogen receptor expression and has been associated with poor survival.[4]

In addition to these observations in human cancers, studies of transformed cells in culture have suggested that malignant cells may escape normal growth regulatory controls by secreting growth factors into their local environment.[5] This phenomenon has been called autocrine growth stimulation. Previously we have explored the role of epidermal growth factor in growth regulation of ovarian cancers. We found that proliferation of some, but not all, ovarian cancer cell lines was increased after treatment with epidermal growth

factor.[6] In this study we have examined epidermal growth factor receptor expression in these cancer cell lines to determine whether there is a correlation between responsiveness to epidermal growth factor and receptor number or affinity. In addition, to elucidate whether changes in epidermal growth factor receptor expression occur during malignant transformation, we have examined epidermal growth factor receptor expression and responsiveness to epidermal growth factor of normal human ovarian epithelial cells in culture.

Material and methods

Cell culture. Five epithelial ovarian cancer cell lines (OVCA 420, OVCA 429, OVCA 432, OVCA 433, and DOV 13) previously established in our laboratory were maintained in monolayer culture in tissue culture medium containing modified Eagle's medium (Hazelton Research Products Inc., Lenexa, Kan.) supplemented with 10% heat-inactivated fetal bovine serum (Gibco Laboratories, Grand Island, N.Y.), sodium pyruvate, nonessential amino acids, glutamine, penicillin, and streptomycin. MK (mouse keratinocyte) cells, which are stimulated to proliferate in the presence of epidermal growth factor, were grown in Spinner's modified minimal essential medium supplemented with 10% heat-inactivated fetal bovine serum.

Epithelial cells were obtained from the surface of normal human ovaries that had been removed at operation for treatment of benign gynecologic disease. The ovaries were transferred aseptically from the operating room to the laboratory, where the epithelial cells were isolated by gently scraping the ovarian surface with a scalpel as previously described.[7] The normal ovarian epithelial cells were maintained in monolayer culture in a 1 : 1 mixture of MCDB105 and M199 media (Sigma Chemical Co., St. Louis) supplemented with 10% heat-inactivated fetal bovine serum. The morphologic appearance of these cells in culture was consistent with epithelium (Fig. 1, *A*). The epithelial nature of the cells was verified by immunohistochemical staining with anticytokeratin antibodies AE1/AE3, which bind to ovarian epithelium but not stroma (Fig. 1, *B* and *C*). Purified mouse immunoglobulin G specific for nonhuman tissue (Coulter Immunology, Hialeah, Fla.) was used as a negative control. In addition, electron microscopy was performed to confirm the presence of apical microvilli. Staining with anti-factor-8 antibody was performed to confirm the absence of contaminating endothelial cells.

Thymidine incorporation assay. Ovarian cancer cells were seeded in 96-well plates (5×10^4 cells per well) in tissue culture medium containing 2% fetal bovine serum and different concentrations of murine epi-

dermal growth factor (0, 0.2, 2, or 20 ng/ml) (Sigma). Six replicate wells were incubated with each concentration of epidermal growth factor. After 18 hours, when the cells were confluent, 1 μCi of thymidine tagged with tritium (6.7 Ci/mmol) (New England Nuclear, Wilmington, Del.) was added to each well. Six hours later the culture medium was removed, the cells were washed three times with phosphate-buffered saline solution and solubilized with 2N sodium hydroxide, and cell-associated radioactivity was determined by scintillation counting. MK cells were used in each experiment as positive controls. The normal ovarian epithelial cells were seeded in 96-well plates (5×10^4 cells per well) in MCDB 105–M199 medium containing 2% fetal bovine serum and then allowed to grow to confluence (2 to 3 days). Epidermal growth factor (0, 0.2, 2, or 20 ng/ml) was then added to the cells for 24 hours. During the final 6 hours, [^{3}H]thymidine (1 μCi/well) also was present in each well. Cells were then washed and lysed with 2N sodium hydroxide, and the cell-associated radioactivity was assessed by scintillation counting.

Epidermal growth factor receptor binding. Ovarian cancer cells and normal ovarian epithelial cells were plated in 24-well plates at 1.1 to 1.7 $\times 10^5$ cells per well in their respective culture media and grown to confluence. The monolayers then were washed with Hank's balanced salt solution and incubated at 37° C for 1 hour in medium containing 10% bovine serum albumin and 0.08% sodium azide. Then medium containing 1% bovine serum albumin, 0.4 ng/ml epidermal growth factor tagged with iodine 125 (specific activity 165 mCi/μg) (Amersham Corporation, Arlington Heights, Ill.) and varying concentrations of unlabeled epidermal growth factor (1.6 to 25 ng/ml) were added to the wells. Assays were performed in triplicate. After incubation for 1 hour at 4° C, the cells were washed three times with medium containing 1% bovine serum albumin and then processed for scintillation counting with a γ-counter. Nonspecific binding was determined by incubation of cells with a hundredfold excess of unlabeled epidermal growth factor. The final number of cells per well for each ovarian cancer cell line and normal epithelial culture was determined for each experiment by trypsinization and counting of separate wells. The binding data were analyzed by the Scatchard method with the Enzfitter software program (Elsevier-Biosoft, Cambridge).

Statistics. Student's t test was used to analyze experiments comparing two means. Adjustment for multiple comparisons was made where appropriate.

Results

The effect of epidermal growth factor on [^{3}H]thymidine incorporation of the ovarian cancer cell lines is shown in Fig. 2, *A*. Epidermal growth factor stimulated a threefold increase in [^{3}H]thymidine incorporation in DOV 13 cells ($p < 0.001$). In addition, a 60% to 70% increase was seen in OVCA 433, OVCA 429, and OVCA 420 cells ($p < 0.01$). Proliferation of OVCA 432 cells was not affected by epidermal growth factor. The data shown in Fig. 2, *A*, were found to be reproducible over the course of multiple similar experiments in which the optimal serum concentration was determined. These optimal conditions are what is described in the Material and methods section. The effect of epidermal growth factor on [^{3}H]thymidine incorporation in the normal ovarian epithelial cells is shown in Fig. 2, *B*. In multiple experiments epidermal growth factor stimulated twofold to fourfold increases in [^{3}H]thymidine incorporation in monolayer cultures of normal ovarian epithelial cells from five patients ($p < 0.01$). In each experiment epidermal growth fac-

tor markedly stimulated [^{3}H]thymidine incorporation in MK cells. In one representative experiment MK cells treated with 20 ng/ml of epidermal growth factor incorporated 8146 ± 1322 counts/min (mean ± SD) of [^{3}H]thymidine compared with 836 ± 132 cpm in cells that did not receive epidermal growth factor.

Scatchard analysis of ^{125}I-EGF binding revealed the presence of high-affinity receptors in all five of the ovarian cancer cell lines (Fig. 3, *A* and *B*) and in the normal ovarian epithelial cells (Fig. 4, *A* and *B*). In the three normal epithelial cell cultures tested, linear Scatchard plots were obtained, which is indicative of a single class of high-affinity receptor (dissociation constant 0.61 to 1.42 nmol/L). Two of five ovarian cancer lines (OVCA 420 and DOV 13) appeared to have a single class of high-affinity epidermal growth factor receptor (dissociation constant 0.29 to 0.69 nmol/L), whereas the other three ovarian cancer cell lines appeared to have two classes of epidermal growth factor receptor of relatively lower and higher affinity (0.32 to 0.40 nmol/L; 1.11 to 1.39 nmol/L) (data not shown). The number of epidermal growth factor receptors per cell ranged from 1 to 1.4×10^5 in the normal ovarian cells and from 3.9×10^4 to 1×10^5 in the ovarian cancer cells (Table I). There was no relationship between epidermal growth factor receptor number or affinity and the effect of epidermal growth factor on [^{3}H]thymidine incorporation.

Comment

Epidermal growth factor is a potent mitogen for a wide range of normal cells in culture. In cells that are grown in culture medium that contains only small amounts of serum, epidermal growth factor usually acts to stimulate striking increases in deoxyribonucleic acid synthesis. In a prior study of human ovarian epithelial cells, Siemens et al.[8] showed that addition of epidermal growth factor to the culture media enhanced plating efficiency and growth. In the present study, we have demonstrated that normal human ovarian epithelial cells express high-affinity epidermal growth factor receptors and that epidermal growth factor consistently

*−, No effect; ÷, 50% to 100% increase; ++, >200% increase.

acts to stimulate deoxyribonucleic acid synthesis in these cells. Although ovarian epithelial cells in vivo, for the most part, are quiescent cells that coat the ovarian surface, it is possible that epidermal growth factor may act to stimulate regrowth of epithelium after disruption of the ovarian surface at ovulation. Since it has been shown that epidermal growth factor is present in follicular fluid,[9] it is appealing to speculate that follicular cells secrete epidermal growth factor, which then acts in a paracrine fashion to stimulate growth of epithelium after rupture of the follicle.

Previously it has been shown that epidermal growth factor may act as a mitogen for various types of human cancer cells in culture.[10, 11] Among the five ovarian cancer cell lines that we studied, one increased proliferation markedly in response to epidermal growth factor (>twofold), three increased proliferation slightly (50% to 100%), and one was unaffected. In addition to our experiments that used immortalized cell lines, others have tested the effect of epidermal growth factor on growth of primary cultures of ovarian cancer cells. Among 16 gynecologic cancers studied by Singletary et al. (13 ovarian, 3 endometrial),[11] proliferation was increased by at least 100% in nine cases. This study, like ours, suggests that some, but not all, ovarian cancer cells are responsive to epidermal growth factor. Even in those cancer cells that respond to epidermal growth factor, however, the magnitude of the mitogenic response usually is less than that of normal cells.

Although several of the molecular events that occur following binding of epidermal growth factor to its receptor have been characterized, including tyrosine phosphorylation, intracellular alkalinization, calcium influx, and prostaglandin synthesis, the relationship between these events and deoxyribonucleic acid synthesis and cellular proliferation is not understood.[1, 2] It is clear, however, that the biologic effects of epidermal growth factor can be initiated only after binding of epidermal growth factor to its specific cell membrane receptor. It has been reported that a proportion of human breast,[4] ovarian,[12] and endometrial[13] cancers express little or no detectable epidermal growth factor receptor; therefore it has been proposed that the loss of responsiveness to epidermal growth factor of cancer cells in culture may be due to decreased receptor expression.

In normal ovarian epithelium, we found a single class of high-affinity binding sites for epidermal growth factor. The three normal ovarian epithelial cultures that were assessed had between 1 and 1.5×10^5 binding sites per cell. The ovarian cancer cell lines all had similar numbers of high-affinity receptors for epidermal growth factor as well. In three cancer cell lines linear Scatchard plots were obtained, indicating a single class of receptor, similar to the normal ovarian epithelial cells. In two cancer cell lines curvilinear Scatchard plots were obtained, consistent with two populations of receptors of different affinities. Although it has been postulated that the biologic effects of epidermal growth factor are mediated via the higher-affinity sites when two classes of receptor are present, this has not been proved and frequently cells that are responsive to epidermal growth factor have only a single class of receptor.[10, 14] Overall, the cancer cell lines had similar numbers of binding sites per cell as the normal ovarian epithelial cells. There was no relationship between epidermal growth factor receptor number or affinity and responsiveness to epidermal growth factor.

The results of this study are similar to those of others that have examined the relationship between epidermal growth factor receptor expression and response to epidermal growth factor in other types of cancers. For example, in a study in which four breast cancer cell lines were tested for mitogenic response to epidermal growth factor, only two were responsive despite the presence of epidermal growth factor receptors in all

cases.[10] In addition, Werner et al.[14] found variable responsiveness to epidermal growth factor in glioma cell lines. Proliferation of cell lines with 10^4 to 10^5 receptors per cell either increased or was unaffected by epidermal growth factor, whereas proliferation of cell lines with $>10^6$ receptors per cell was inhibited by epidermal growth factor. Similarly, epidermal growth factor inhibits proliferation of the A431 cell line, which markedly overexpresses the epidermal growth factor receptor.[15] None of the ovarian cancer cell lines that we have tested expressed such high levels of receptor nor was growth inhibition by epidermal growth factor observed.

The results of the present study indicate that the decreased mitogenic effect of epidermal growth factor in ovarian cancer cell lines relative to normal ovarian epithelium is not due to an absence of cell surface epidermal growth factor receptors. It is possible, however, that the attenuated response to epidermal growth factor could be due to alterations in the downstream signals involved in transmitting the mitogenic signal from the receptor to the nucleus. As these complex pathways are elucidated in the future, we will test their functional integrity in these ovarian cancer cell lines. Alternatively, it is possible that the ovarian cancer cell lines do not respond to exogenous epidermal growth factor because they already are maximally growth stimulated because of the production of other growth stimulatory factors or because of inactivation of tumor suppressor genes.

Prenatal diagnosis of myotonic muscular dystrophy with linked deoxyribonucleic acid probes

Aubrey Milunsky, MB, BCh, DSc, DCH, James C. Skare, PhD, Jeffrey M. Milunsky, BA, Thomas A. Maher, BS, and Jean A. Amos, PhD

Boston, Massachusetts

Since the localization of the myotonic muscular dystrophy gene, closer deoxyribonucleic acid markers have been discovered. These now facilitate both presymptomatic and prenatal diagnosis of myotonic muscular dystrophy. We report our prenatal diagnosis experience with six cases in five families. Obstetricians are advised to inform their patients with a family history of myotonic muscular dystrophy of these testing opportunities. The fetus of the mother with myotonic muscular dystrophy who remains in utero until term is at considerable risk, as is the mother herself, of serious obstetric complications. (AM J OBSTET GYNECOL 1991;164:751-5.)

Key words: Myotonic muscular dystrophy, DNA, prenatal diagnosis

Myotonic muscular dystrophy is the most common form of muscular dystrophy in adults.[1] Women who are affected by this serious autosomal-dominant disorder may be free of symptoms or have minimal signs, yet they have a 50% risk of having a child with severe congenital myotonic muscular dystrophy. Indeed, although men and women with myotonic muscular dystrophy have the same 50% risk of transmitting it, the offspring of affected women are invariably more seriously affected.[1] Various other alternative mechanisms have been proposed, including mitochondrial inheritance, genetic imprinting, or a humoral factor.[1] Hence determination of a family history of myotonic muscular dystrophy will facilitate recognition of women at risk, albeit of those who are still free of symptoms. Since the localization of the myotonic muscular dystrophy gene to chromosome 19,[2] closer deoxyribonucleic acid (DNA) markers have been discovered.[3-7] These advances have facilitated the use of DNA probes for prenatal diagnosis of myotonic muscular dystrophy. DNA linkage studies in informative families provide results with high degrees (96% to 99%) of certainty, which are consistent with but not diagnostic of, myotonic muscular dystrophy. Thus far, only one team[8, 9] has reported on successful prenatal diagnosis of myotonic muscular dystrophy with these techniques. We report our experience with five families who sought prenatal studies through our DNA Diagnostic Laboratories, two of which were earlier noted by abstract.[10]

Patients and methods

Families studied. Blood samples from key family members were sent to us by overnight express mail for DNA analysis from physicians elsewhere in the United States. When possible, family informativeness was determined before amniocentesis or chorionic villus sampling. Cultivation of amniotic fluid cells for about 14 days yielded sufficient DNA for molecular analysis. Chorionic villus sampling enabled direct DNA extraction and analysis with results within 10 days.

Pedigrees of the five families with myotonic muscular dystrophy that were studied are shown in Fig. 1; genotypes for each family member appear below each pedigree symbol. In accordance with Griggs et al.,[11] we confirmed that one or more individuals had been accurately characterized as having myotonic muscular dystrophy before linkage studies were undertaken.

Genetic analyses. Genomic DNA was prepared directly from peripheral lymphocytes and cultivated amniotic fluid cells by nuclear pellet isolation and lysis, protease digestion, phenol extraction, and ethanol precipitation.[12] Chorionic villi were lysed in a similar manner and processed as for blood. Restriction digestion and Southern blot analysis of restriction fragment length polymorphisms were performed with standard procedures with the probes shown in Table I.

Each available family member was studied with each of the probe/restriction combinations that are shown in Table I. Prenatal diagnoses were made with the closest restriction fragment length polymorphisms to the myotonic muscular dystrophy gene that was polymorphic in each family. The most likely order of the polymorphic loci that were used in these analyses and the myotonic muscular dystrophy locus is BCL3–ApoC2–CK MM–myotonic muscular dystrophy[5, 7]; BCL3 lies approximately 4 cM from the myotonic muscular dys-

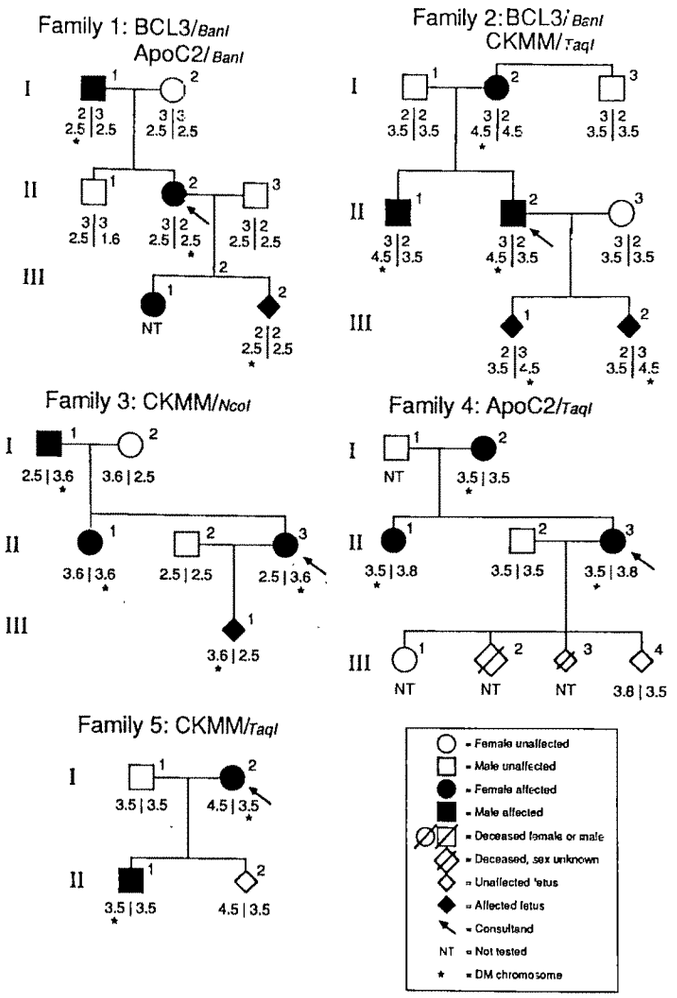

Fig. 1. Pedigrees and individual genotypes of five families who requested prenatal genetic studies.

trophy gene and ApoC2 and CK MM are both within 1 cM of the locus.

Plasmid DNA inserts were labeled by random primer synthesis with [^{32}P]αCTP, (3200 Ci/mmol) (Amersham) to a specific activity $>10^8$ cpm/μg.[13] Membranes were prehybridized, hybridized, washed, and exposed to x-ray film according to a method described elsewhere.[14]

Family 1. A mildly affected mother (II-2) with a previously affected child, aged 9 months (III-1), with joint contractures and developmental delay, elected to have prenatal diagnosis in her second pregnancy (Fig. 1). She declined our request for a blood sample from her first child. Earlier,[13] our DNA linkage data showed with a high degree of certainty that the proband (II-2) was affected, with the use of the Southern blot assay with BCL3/*Ban* I. With the same probe and enzyme, we then demonstrated that the fetus had inherited the maternal myotonic muscular dystrophy mutation with 96% certainty. In addition, nonpaternity for II-1 was discovered with ApoC2/*Ban* I.

The parents elected to continue this pregnancy, which was uneventful. Elective cesarean section was done because of a previous cesarean section. A daughter, who weighed 2980 gm, was delivered. Major respiratory difficulties were encountered immediately and Apgar scores were 5 at 1 minute and 6 at 5 minutes. Even at 30 minutes after birth, severe acidosis (pH 7.1) was present. Typical physical features of myotonic muscular dystrophy were noted and included a hanging open mouth, downturned palpebral fissures, a dull expression, absence of Moro, suck, and gag reflexes, extreme hypotonia with little limb movement, flexion of limb joints, bilateral talipes equinovarus, and ulnar deviation of the hands.

Recurrent episodes of apnea characterized the next 37 days in hospital, during which time mechanical ventilation was necessary. Complications included gastric hemorrhage, jaundice, and a patent ductus arteriosus, which required ligation. Gradual improvement occurred until 6 weeks after birth when the child was

discharged home with an apnea monitor. Prognosis for normal neurologic development was guarded.

Family 2. The consultand (II-2) and his wife requested prenatal diagnosis. His mother (I-2) had indisputable signs of myotonic muscular dystrophy, and he and his brother were considered to be affected in view of cataracts in both, which were diagnosed by examination with a slit lamp. Neither brother had experienced other symptoms or signs of myotonic muscular dystrophy. DNA analysis demonstrated that both sons (II-1 and II-2) had inherited the maternal myotonic muscular dystrophy mutation with 96% certainty, with the use of BCL3/*Ban* I. Prenatal diagnosis of an affected fetus was accomplished, after chorionic villus sampling for III-1, with the same probe and enzyme, as well as with CK MM/*Taq* I. The parents elected to terminate this pregnancy. No tissues were received for further study after termination. A second pregnancy was studied, and again a prenatal diagnosis of an affected fetus (III-2) was made. Once again, the parents elected to terminate this pregnancy. No tissue was received for further study.

Family 3. The consultand, who had symptoms (II-3), and her husband requested prenatal diagnosis. Earlier studies of her sister who had symptoms (II-1), her affected father (I-1), and the other family members showed that the consultand had inherited the same allele from her affected father. Prenatal diagnosis of myotonic muscular dystrophy for III-1 was made with CK MM/*Nco* I with 99% certainty. The parents elected to continue the pregnancy, and an affected child was born, as predicted.

After breech presentation, delivery by cesarean section because of intrauterine growth retardation and a known prenatal diagnosis of myotonic muscular dystrophy occurred without incident at 38 weeks' gestation. The female infant weighed 2200 gm and had Apgar scores of 5 at 1 minute and 7 at 5 minutes. Mild respiratory distress was detected immediately and successfully treated. She had myotonic facies, and very poor Moro, rooting, suck, and grasp reflexes. Marked hypotonia was evident. Diaphragmatic paralysis on the right side was demonstrated by chest x-ray films. Marked hyperbilirubinemia occurred but rapidly disappeared. Hospital discharge occurred at 1 week after birth. By 7 weeks of age, the child was doing well, had no real evidence of myotonia, was gaining weight, and had no pulmonary symptoms.

Family 4. The consultand (II-3) requested prenatal diagnosis for her fourth pregnancy. Her first pregnancy resulted in a girl with no congenital features of myotonic muscular dystrophy. Her second child died after aspiration of meconium 1 hour after birth. The third pregnancy ended in fetal death, possibly because of trisomy 13 syndrome. The consultand, her sister (II-1), and their mother (I-2) had clinical diagnoses of myotonic muscular dystrophy. Seven other siblings (not shown) had not been clinically evaluated and were not included in this analysis.

The informativeness study revealed that the myotonic muscular dystrophy allele in this family was transmitted with the maternal 3.5 kb ApoC2/*Taq* I allele. The consultand transmitted her paternal 3.8 kb allele to her fetus, which allowed us to predict that it would be unaffected with a certainty >98%. A healthy infant was delivered and DNA studies confirmed the prenatal diagnosis.

Family 5. The affected consultand (I-2) had previously had a son (II-1) with myotonic muscular dystrophy. In this, her second pregnancy she requested prenatal diagnosis at 22 weeks' gestation for late pregnancy management. The family study revealed that the myotonic muscular dystrophy allele was transmitted on the maternal chromosome 19 and bore the linked 3.5 kb CK MM/*Taq* I allele. The consultand transmitted her 4.5 kb allele to her fetus, which allowed a diagnosis of an unaffected child with >99% certainty. Pregnancy was uneventful, and a healthy daughter was delivered by cesarean section because of a previous cesarean section.

Comment

Myotonic muscular dystrophy was first detected prenatally, by means of genetic linkage with the secretor locus.[15, 16] This method was limited because of the few informative families, as well as because of the possibilities of missed diagnoses that were due to a recombination rate of approximately 10%. Assignment of the myotonic muscular dystrophy locus to chromosome 19 and the subsequent isolation of polymorphic, tightly linked DNA probes have now facilitated prenatal diagnosis with high degrees of accuracy. In this report we document the prenatal diagnosis of an affected fetus in four of six pregnancies at risk. Either chorionic villus sampling or amniocentesis provided adequate cellular samples. Regardless of tissue source, however, prenatal diagnostic studies should be attempted only after proper documentation of an affected family member has been established and formal genotypes of informative family members have been determined.

DNA studies provide a high degree of certainty that the myotonic muscular dystrophy gene has been inherited. This is especially important in a prospective mother and thereby alerts the obstetrician to probable serious maternal and perinatal complications (Table II).

All reviews of pregnancy with myotonic muscular dystrophy[1, 18-20] have pointed to an increased rate of complications. Many reports have involved single or few cases, and the real frequency of specific complications remains uncertain. However, a larger study by O'Brien and Harper[19] of 102 pregnancies among 35 affected women who had 83 infants has yielded a slightly better estimation of the rate of pregnancy com-

plications when compared with normal pregnancies. Although an increased frequency of the complications that are listed in Table II may indeed occur in women with myotonic muscular dystrophy, thus far statistical significance can be claimed only for retained placenta, placenta previa, hydramnios, elected cesarean section, and neonatal death.[19] Hydramnios is thought to result from inadequate fetal swallowing in pregnancies in which the fetus has myotonic muscular dystrophy.

A prolonged first stage of labor, poor uterine contractions, and reduced voluntary muscle power in the second stage have all been cited.[1] Many authors have warned of major complications after general anesthesia or surgery, even when women with myotonic muscular dystrophy are mildly affected.[1, 19] Some authors have advised that general anesthesia be avoided when possible and have indicated that neostigmine, other cholinesterase inhibitors, and succinylcholine-like drugs, which may cause contractions, should not be used. Others have emphasized the intraoperative occurrence of cardiac arrhythmias during general anesthesia.[20] Use of thiopental may result in severe apnea in patients with myotonic muscular dystrophy.

Harper[1] has pointed to preeclampsia as the only complication for which frequency seems to be reduced in myotonic muscular dystrophy. This finding is probably due to the lowering of blood pressure in myotonic muscular dystrophy.

When parents are weighing the decision to have prenatal diagnostic studies performed or whether to abort an affected fetus, they will need to know about the increased frequency of mental retardation, progressive weakness and wasting, hypogonadism, and the increased mortality in young adulthood,[1, 19] particularly in the affected children of mothers with myotonic muscular dystrophy.

Obstetricians who have secured a prenatal diagnosis of myotonic muscular dystrophy in a continuing pregnancy are advised to have a neonatologist present for the delivery, given the known serious potential perinatal complications.

In families with a history of myotonic muscular dystrophy, presymptomatic testing, with molecular analysis as described, can now be offered. For those family members who are found to be affected, albeit without symptoms, prenatal diagnosis is now available with high degrees of certainty. Although elective abortion is one option, anticipation, prevention, or expeditious treatment will enable the physician to diminish the likelihood of maternal morbidity and neonatal morbidity and mortality if he or she has the results from presymptomatic, confirmatory, and prenatal diagnoses.

There are inherent limitations of DNA linkage analyses, and these are primarily (1) the possibility of recombination, (2) the inability to distinguish which chromosome of a pair contains the mutation, (3) only one affected family member, (4) deceased parents without a known diagnosis of myotonic muscular dystrophy, (5) unexpected discovery of nonpaternity, and (6) lack of family cooperation in providing medical data and/or blood samples. Notwithstanding such limitations, studies in our DNA diagnostic laboratories show that 17 of 19 (89.5%) families that were studied have been informative, and consultands have been able to obtain valuable information.

Development of even closer, flanking markers to the

myotonic muscular dystrophy locus will shortly further increase the accuracy of these studies. Application of the polymerase chain reaction technology will soon allow us to provide results within days of sample receipt.

We thank B. Wieringa, PhD, T. McKeithan, PhD, and R. J. Bartlett, PhD, for probes they provided, R. G. Korneluk, PhD, for assistance with studies on one family, and the physicians and genetic centers for referring these families to us for study.

Addendum

We studied two additional families. In one, an affected fetus was detected, and pregnancy is continuing. In the other, the fetus was not affected by myotonic dystrophy but had hydrocephalus and other major anomalies at birth. Family 2 (Fig. 1) had a third pregnancy with twins, one being detected through analysis of chorionic villi as affected with >99% certainty. Selective termination was elected and pregnancy with the remaining fetus continues.

Prevention of preterm birth in high-risk patients: The role of education and provider contact versus home uterine monitoring

Donald C. Dyson, MD,[a] Yvonne M. Crites, MD,[a] Deborah A. Ray, MD,[a] and Mary Anne Armstrong, MA[b]

Santa Clara and Oakland, California

A total of 394 patients were enrolled in a study to assess the effectiveness of an educational preterm delivery prevention program and to determine whether the addition of home uterine monitoring to the program improved results in patients at high risk of preterm labor. Both the educational program and home uterine monitoring were found to increase the percentage of women with preterm labor who sought care while still favorable for long-term suppression, resulting in a decreased incidence of preterm births and improved outcome when compared with similar high-risk patients who did not participate in these programs. In a randomized, prospective study, addition of home uterine monitoring to the educational program was found to significantly improve outcome in twin gestations but not in singleton gestations. However, the number of singleton pregnancies was too small to rule out possible benefit from home uterine monitoring in that group. (AM J OBSTET GYNECOL 1991;164:756-62.)

Key words: Premature labor, fetal monitoring, prenatal care, tocolysis

Preterm birth remains the main cause of perinatal mortality and morbidity.[1] Despite the increasing use of tocolytic agents, the incidence of preterm birth has remained unchanged.[2] The effect of tocolytic therapy has been severely limited because 70% to 80% of patients in whom preterm labor develops do not seek care until they have ruptured membranes or advanced cervical dilation, making long-term successful tocolysis unlikely.[3, 4] Recognition of the importance of early detection of preterm labor led to development of preterm delivery prevention programs that stressed identification of high-risk patients, patient education, self-palpation for uterine contractions, and frequent cervical examinations.[5] Although not uniformly successful,[6, 7] most studies have found this educational approach to be asssociated with a substantial increase in the percentage of patients with preterm labor who seek care while they are still favorable for suppression, with a resultant decrease in the incidence of preterm births.[5, 8-10]

Katz et al.[11] showed that overt clinical preterm labor is usually preceded by a period of increased uterine activity that is readily detected by tocodynamometry. Subsequent studies showed that daily home monitoring of uterine activity in high-risk patients also appears effective in increasing the proportion of patients with preterm labor who seek care while they are favorable for suppression, with a resultant decrease in the incidence of preterm births.[4, 12] However, other studies[13, 14] questioned whether it was the monitoring, data from the monitoring, or the patient education and nursing contact that was provided with the monitoring service that was responsible for the improved outcome. The purpose of the present investigation is twofold: (1) to document whether implementation of an organized preterm delivery prevention program results in an improved outcome in patients at high risk of preterm labor, and (2) with the use of a randomized, prospective design, to assess whether the addition of home uterine monitoring to the preterm delivery prevention program would further improve outcome.

Material and methods

Between Jan. 1, 1986, and Jan. 1, 1989, patients who received prenatal care at the Kaiser Permanente Medical Center, Santa Clara, Calif., were prospectively assessed for the following risk factors: twin gestation, preterm delivery at <34 weeks' gestation after premature labor or premature rupture of membranes in the preceding pregnancy, premature labor requiring parenteral tocolysis but with term delivery in the preceding pregnancy, incompetent cervix with cerclage in place, and nullipara with bicornuate, subseptate, or di-

delphic uterus. A total of 253 patients with these risk factors identified before 28 weeks' gestation and without evidence of preterm labor in the current pregnancy, were asked to participate in this study. Two patients refused and 251 patients (99%) gave informed consent and were enrolled. At 24 weeks' gestation, all patients received an initial educational session concerning the signs and symptoms of preterm labor, were taught the technique of self-palpation for uterine activity, and were followed up with weekly cervical examinations. All patients were provided monitors (DT-100, Advanced Medical Systems, Hamden, Conn.) for home uterine monitoring. According to the protocol approved by the Institutional Review Board of the Kaiser Foundation Research Institute, patients were randomized into two groups: the home uterine monitoring group, in which the home uterine monitoring tracings were analyzed and used in patient management, and education-palpation group, in which home uterine monitoring tracings were not analyzed or used in patient management. Patients in the education-palpation group routinely transmitted to a monitor in such a way that the nurse could tell which patients had transmitted but could not analyze uterine activity data. On rare occasions, patients in the education-palpation group erroneously transmitted to a different monitor. When this occurred, the protocol was for the nurse to not analyze or respond to the tracing. The charts of all patients in the education-palpation group who experienced preterm labor were reviewed, and in no case did it appear that a patient in the education-palpation group was referred by a nurse for increased uterine activity detected by one of these accidentally unblinded tracings. Patients were not aware of their group assignments. All patients were initially asked to monitor themselves 1 hour every day and transmit daily. On Jan. 1, 1988, the protocol was changed to twice-daily monitoring and transmission, and patients in the home uterine monitoring group were given the capability of transmitting an emergent tracing at any time. All patients were asked to record the presence or absence of signs and symptoms of preterm labor and the number of contractions by palpation.

All patients were contacted at least 5 days per week by a study nurse to elicit signs or symptoms of preterm labor, record the number of contractions by palpation, and, in the home uterine monitoring group, to review the monitoring information. All patients were instructed to report to the hospital for evaluation if they had more than five contractions per hour that persisted for more than 1 hour despite lateral bed rest and oral hydration. Asymptomatic patients in the home uterine monitoring group who had more than five contractions per hour on routine monitoring were instructed to lie down, drink fluids, and remonitor for 1 hour. If they persisted with more than five contractions per hour they were referred for evaluation.

All patients in this study were evaluated and treated at Kaiser Foundation Hospital, Santa Clara, Calif., with clinical protocols that recommended tocolysis for persistent uterine contractions if the cervix was already dilated to 2 cm but otherwise required documented cervical change before tocolysis. Prophylactic tocolytic agents were not administered to any patients in this study. Choice of tocolytic agents used was determined by clinical protocol and physician preference and was neither affected by nor did it differ by study groups. If tocolysis was successful, patients were discharged home to bed rest taking oral tocolytic agents and maintaining their pretreatment group protocols. In the home uterine monitoring and education-palpation groups, the dosage of oral tocolytic agent was adjusted to maintain fewer than six contractions per hour on monitoring and on palpation, respectively. Oral tocolysis and monitoring were discontinued at 36 weeks' gestation. Patients who were delivered of infants at <36 weeks' gestation were classified as either a result of failed tocolytic therapy or as indicated preterm births. All gestational ages were confirmed by first- or second-trimester ultrasonography.

A group of 143 patients with the same risk factors for preterm labor who received their prenatal care and were delivered of infants at the same hospital in the 30 months immediately preceding the start of the prospective study was identified as the standard care group. To avoid adverse selection, particular care was taken to select patients by the presence of the risk factor and not the outcome. The same clinical protocols for assessment and treatment of preterm labor were in effect during both the control and study time periods. In this study, preterm labor was diagnosed only if there were persistent uterine contractions (>5 hours) associated with either 2 cm of cervical dilation or documented cervical changes. Favorable for suppression was defined as intact membranes and cervix dilated ≤2 cm. Respiratory distress syndrome was diagnosed if there was a neonatal oxygen requirement that lasted >24 hours and a compatible x-ray film of the chest. Statistical analysis was performed with the χ^2 test, the Fisher exact test, or the Student t test, as appropriate. Results are expressed as mean ± SEM. All p values of ≤0.10 were reported in the tables.

Results

A total of 394 patients were enrolled in the study. Four patients (1.6%), two patients each from the home uterine monitoring and education-palpation groups, subsequently elected to drop out of the study, resulting in a total of 247 patients in the randomized study and 143 in the control group. Of these, 189 were twin ges-

tations and 201 were singleton gestations. Analysis by risk factor in patients with singleton gestations revealed no statistically significant differences in outcome; however, significant differences were found between patients with singleton gestations and those with twin gestations. Results are therefore presented separately for singleton and twin gestations.

Singleton gestations. The distribution of risk factors for preterm labor was similar among all three groups of patients. One previous preterm birth was the indication in 63% of the standard care group, 65% of the education-palpation group, and 56% of the home uterine monitoring group; two or more previous preterm births was the indication in 17%, 16%, and 23% in the standard care, education-palpation, and home uterine monitoring groups, respectively. The mean number of unscheduled visits to rule out preterm labor was greater in both the education-palpation (1.4) versus the standard care group (0.2, $p = 0.01$) and in the home uterine monitoring (1.8) versus the standard care group (0.2, $p = 0.01$). The difference between the education-palpation and home uterine monitoring groups was not statistically significant. As shown in Table I, the difference in incidence of preterm labor was not statistically significant when comparing the three groups in pairs; however, the incidence of preterm birth was markedly less in the education-palpation group than in the standard care group. The incidence of preterm birth also appears to be less in the home uterine monitoring group than in the standard care group, but the difference reached statistical significance only for those delivered of infants at <34 weeks' gestation, specifically because of failed tocolysis. There was no apparent difference between the education-palpation and home uterine monitoring groups. Table II shows that although there were definite trends toward higher birth weights, shorter infant hospital stays, fewer infants admitted to the intensive care nursery, and fewer infants who developed respiratory distress syndrome in both the education-palpation and home uterine monitoring groups when compared with the standard care group, only the shorter infant stay in the standard care versus education-palpation comparison reached statistical significance.

In all three groups, patients with preterm labor at <34 weeks' gestation had aggressive tocolytic therapy unless there were contraindications. Management of patients with onset of preterm labor between 34 and 36 weeks' gestation was less uniform and was characterized by less aggressive use of tocolytic agents and occasionally nontreatment, especially after 35 weeks' gestation. Outcome data are thus reported for both 34 and 36 weeks' gestation. Table III shows indicators of pregnancy outcome in only those patients with onset of pre-

term labor at <34 weeks' gestation. A much higher proportion of patients in the education-palpation and home uterine monitoring groups were seen while still favorable for suppression, with a resultant improvement in success rate of both short-term (>48 hours) and long-term (delivery after 34 weeks' gestation) suppression. Correspondingly, neonatal outcome as measured by birth weight, percent with intensive care nursery admission or respiratory distress syndrome, and duration of infant hospital stay all were significantly improved in both the home uterine monitoring and education-palpation groups as compared with the standard care group. There was no apparent difference between home uterine monitoring and education-palpation groups in any of the factors in Table III.

Twin gestations. There were no statistically significant differences between groups in the patient demographics including maternal age, gravidity, parity, percent nulliparous, and percent with previous preterm delivery. Table IV shows that whereas the incidence of preterm labor was similar in all three groups, the incidence of preterm birth was decreased in the education-palpation group and markedly decreased in the home uterine monitoring group compared with the standard care group. The incidence of patients delivered of premature infants as a result of failed tocolytic therapy at <34 weeks' gestation was decreased by 53% in the education-palpation group and by 74% in the home uterine monitoring group as compared with the standard care group ($p = 0.05$ and 0.01, respectively). Table V shows that infants in the education-palpation group tended to have a better outcome than those in the standard care group and were significantly less likely to be admitted to the intensive care nursery, develop respiratory distress syndrome, and experience neonatal death than were the infants in the standard care group. Infants in the home uterine monitoring group clearly had the best neonatal outcome, having shown highly significant improvements in all indicators of neonatal outcome as compared with the infants in the standard care group and were significantly less likely to have weighed <1500 gm, to have been admitted to the intensive care nursery, and to have had a shorter hospital stay as compared with the infants in the education-palpation group.

Table VI shows that patients with twin gestations in whom the onset of preterm labor developed before 34 weeks' gestation had similar gestational ages when that

occurred. However, gestational age at delivery was significantly improved in both the education-palpation and home uterine monitoring groups as compared with the standard care group. Once again, this appeared to be a result of a higher percentage of patients who were seen while still favorable for suppression, resulting in improved short-term and long-term tocolysis and improved neonatal outcome in both the education-palpation and home uterine monitoring groups. Table VI also shows that whereas both the education-palpation and home uterine monitoring groups showed an improved outcome compared with the standard care group, the home uterine monitoring group had the best outcome; the home uterine monitoring group had a statistically significant improvement in the percentage of patients seeking care while still favorable for suppression, in effectiveness of short-term and long-term tocolysis, and in all indicators of neonatal outcome as compared with the education-palpation group.

Comment

The success of tocolytic therapy is highly dependent on the status of the cervix and membranes at the initiation of tocolysis.[15] Early detection and treatment of preterm labor has been advocated as the key factor in the prevention of preterm births.[5] Unfortunately, studies have suggested that 70% to 80% of women in whom preterm labor develops are seen only after they have ruptured membranes or have advanced cervical dilation, making successful longer-term tocolysis unlikely.[3, 4] Our study confirms these findings, with 69% of women with singleton pregnancies and 73% of those with twin gestations in our standard care group who experienced preterm labor seeking care when they were no longer favorable for long-term tocolytic therapy.

Our study agrees with previous reports[5, 8-10] that suggest that participation in an organized preterm delivery prevention program that emphasizes patient education and frequent provider contact can significantly increase the percentage of high-risk patients in whom preterm labor develops who seek care while still favorable for suppression, thus increasing the success of tocolysis and decreasing the incidence of preterm birth. In our study, the percentage of women with preterm labor who sought care while still favorable for suppression increased from 31% to 84% in singleton and from 27%

to 68% in multiple gestations after initiation of such a preterm delivery prevention program (education-palpation group), and the incidence of preterm birth at <34 weeks' gestation subsequently decreased by 54% in singleton gestations and by 41% in twins.

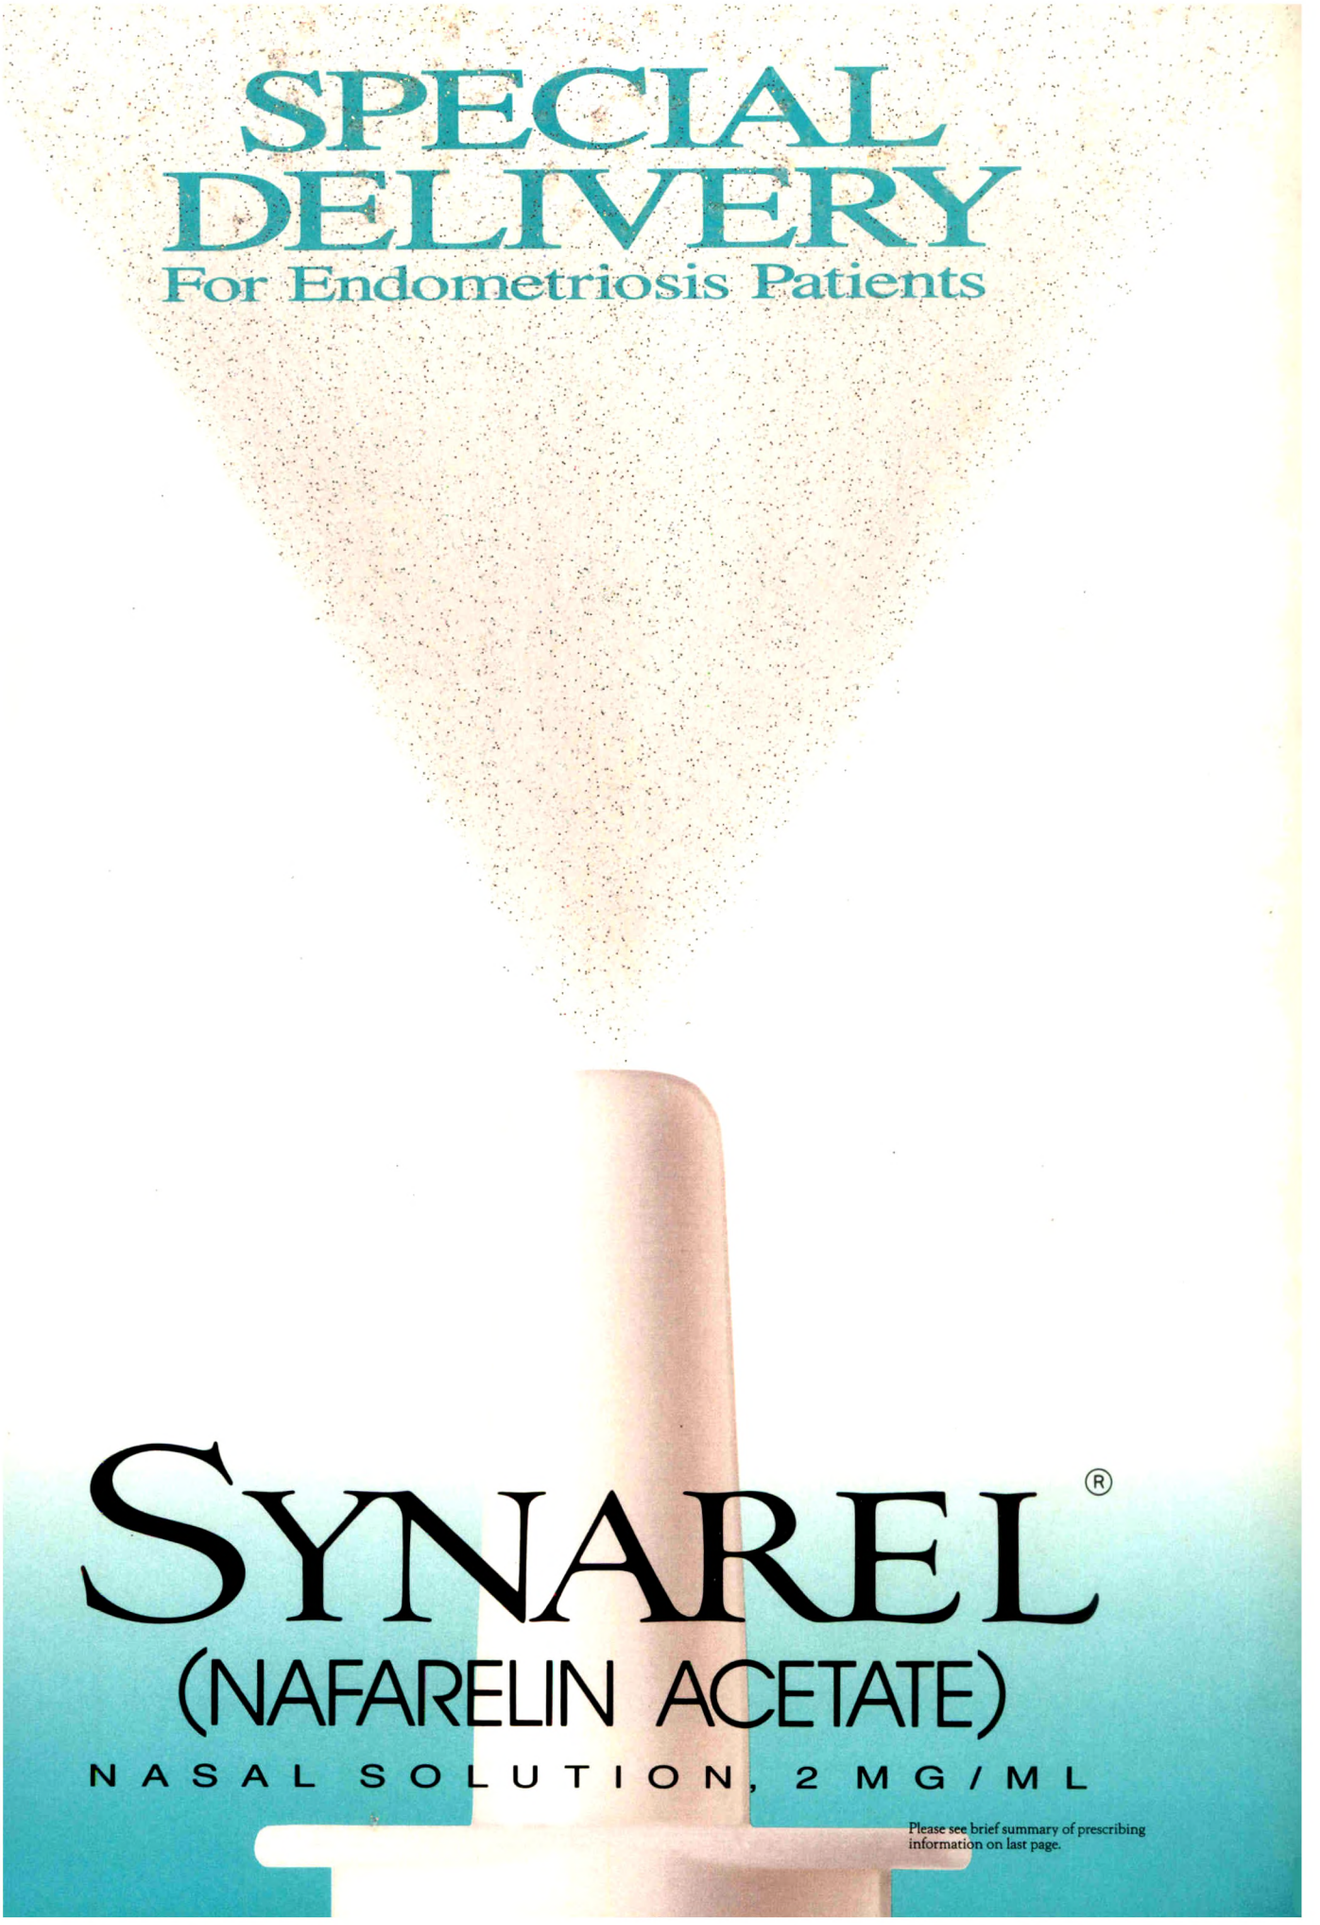
Our study also agrees with previous reports[4, 12] that suggest that daily home monitoring of uterine activity in high-risk patients can also increase the early detection of preterm labor, allowing more successful treatment and improved outcome. In our study, the percentage of patients with preterm labor who sought care while still favorable for suppression increased from 31% to 68% in singleton and from 27% to 96% in multiple gestations in the home uterine monitoring group, and the incidence of preterm birth at <34 weeks' gestation decreased by 50% in singleton and by 66% in multiple gestations, resulting in a highly significant improvement in all indicators of neonatal outcome in the home uterine monitoring group compared with the standard care group.

Our study strongly suggests that both the educational approach and home uterine monitoring are effective in the improvement of outcome in patients at high risk of preterm labor. However, in the home uterine monitoring group, the question[14] as to whether it is the monitoring information or the frequent nursing contact that occurs in conjunction with home uterine monitoring that results in improved outcome is more difficult to answer. In singleton pregnancies, within the limits of our study design, there was no apparent difference in outcome between the education-palpation and home uterine monitoring groups. However, in patients with twin gestations, use of home uterine monitoring information resulted in an increase in those with preterm labor favorable for suppression from 68% to 96% and an increase in the success of both short-term (76% to 100%) and long-term (52% to 82%) tocolysis compared with the education-palpation group. Although the 45% reduction in preterm births before 34 weeks' gestation did not reach statistical significance, there was a significant reduction in both births of <1500 gm and admissions to the intensive care nursery as well as shorter infant hospital stays in the home uterine monitoring group compared with the education-palpation group. Thus our study suggests that for patients with a twin gestation, the addition of home uterine monitoring information will improve outcome even if they are already participating in an intense preterm delivery prevention program with frequent provider telephone contact.

There are several possible explanations as to why home uterine monitoring was found to be more beneficial in twin gestations than in singleton gestations in this study. It has been reported that patients with multiple gestations perceive contractions less accurately than do patients with singleton gestations.[16] In multiple gestations, this decreased perception may limit the effectiveness of programs that depend on the mother's ability to perceive or detect contractions. The possible bias of nurses who have occasional accidental knowledge of home uterine monitoring data in education-palpation patients is an unlikely explanation of the failure to find a difference in singleton gestation because the same nursing protocols were used with twin gestations in which significant improvement was found with home uterine monitoring. The use of six contractions per hour as the threshold, instead of the more commonly used four contractions per hour, is also an unlikely explanation of the failure to find efficacy in home uterine monitoring in singletons because only one patient in the singleton home uterine monitoring group was found to have had between four and six contractions per hour on the last tracing before diagnosis of preterm labor. However, the design of our study may have acted to minimize the differences in outcome between the home uterine monitoring and education-palpation groups. Patients in the education-palpation group were contacted at least 5 days per week by telephone. This is a much higher standard of care than that found in most preterm delivery prevention programs. Patients in the education-palpation group also received a home monitoring device. Although the monitoring information was not used, presence of a monitor may well have decreased the dropout rate and increased the compliance in the education-palpation group. In addition, the lower rate of preterm labor and the relatively small number of patients in our singleton groups would make it more difficult to detect a true difference. With the size of our singleton groups, to have a power of 80% would require a 75% or larger reduction in preterm births in the home uterine monitoring group (20% to 5%), with a two-tailed hypothesis test and a significance level of 0.05. Our numbers are thus too small to reasonably expect to detect a reduction in preterm labor as a result of uterine monitoring of <75% in our singleton groups.

In summary, our patient population consists predominantly of compliant patients from the middle socioeconomic class with a relatively low incidence of drug abuse and infection complications, so that these interventions may not be as successful in other dissimilar patient populations. In our study, both an organized preterm delivery prevention program with the use of frequent telephone contact with nurses and a home uterine monitoring program were found to significantly improve outcome in patients at high risk of preterm labor compared with our previous standard of care. In our study, the addition of home uterine monitoring in patients with twin gestations resulted in improved outcome as compared with those patients man-

aged with frequent telphone contact with nurses only. The issue of efficacy of home uterine monitoring in singleton pregnancies at high risk of preterm labor remains unresolved and awaits further clinical trials. However, our own internal cost analysis suggests that providing the same intense preterm delivery prevention program with frequent nursing contact but deleting the home uterine monitor would result in only a 17% cost saving. Thus on the basis of our study and others,[5, 8-10] it appears that patients with singleton gestations who have major risk factors of preterm labor benefit greatly from participating in a preterm delivery prevention program. If the components of a preterm delivery prevention program (patient education and frequent provider contact) cannot otherwise be made available to these high-risk patients, which is often the case in clinical practice, then home uterine monitoring may be a reasonable alternative. From our study, it also appears that home monitoring of uterine activity is the most effective method to decrease the preterm birth rate in twin gestations. Whereas the increased use of these intense intervention programs should substantially decrease the preterm birth rate in high-risk patients, our ability to minimize the overall preterm birth rate will continue to be limited as long as 40% to 60% of preterm births continue to occur in patients with no identifiable risk factors for preterm labor.[5, 6]



We gratefully acknowledge Elizabeth Wellman, RN, and Jane Dyson, RN, for their invaluable assistance with this study and Bruce Folck for computer programming.

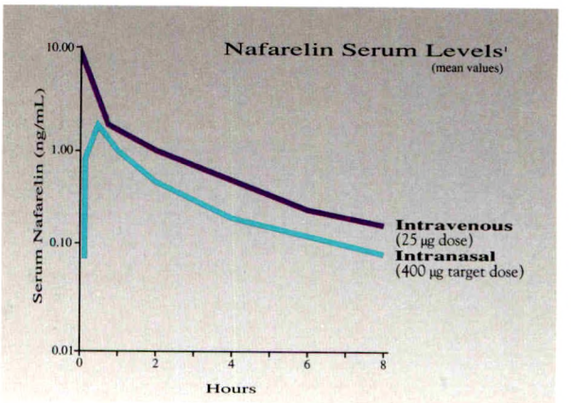
SPECIAL DELIVERY

For Endometriosis Patients

SYNAREL®

(NAFARELIN ACETATE)



NASAL SOLUTION, 2 MG/ML

Please see brief summary of prescribing information on last page.

The Only GnRH* Agonist With The Dosing Distinction Of Intranasal Delivery

- Intranasal administration produces nafarelin serum levels comparable to I.V. dosing: In pharmacokinetic studies, SYNAREL was rapidly absorbed into systemic circulation following intranasal administration, with maximum serum concentrations achieved between 10 and 40 minutes.[1]

- B.I.D. controlled-dose intranasal administration provides serum estradiol levels that result in outstanding clinical efficacy, while producing minimal impact on bone and a predictable hypoestrogenic profile.†
- Facilitates ease of patient management should allergic or other adverse events occur.
- Retreatment cannot be recommended since safety data for retreatment are not currently available.

1. Syntex document #829-223-A.

*Gonadotropin-releasing hormone analog.

†There is a small, largely reversible loss in bone density with 6-month treatment. Use of SYNAREL for longer than the recommended 6 months or in the presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a non-hormonal method of contraception when taking SYNAREL.

Please see adjacent page for brief summary of prescribing information.

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (±SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

CURRENT PROBLEMS IN OBSTETRICS, GYNECOLOGY AND FERTILITY

Editor-in-Chief: Robert L. Barbieri, MD
State University of
New York at Stony Brook

Current Problems in Obstetrics, Gynecology and Fertility brings you the authoritative, practical information you need to stay current in your specialty and to provide the best possible care to patients.

- Each bimonthly issue provides in-depth, monograph-length coverage (40-60 pages) of a clinical topic of vital interest to practitioners today.
- Topics are selected for relevance to your daily practice: preconceptual counseling, infertility, endocrine problems, high-risk obstetrics, diagnosis and treatment of primary and secondary amenorrhea, pediatric and adolescent gynecology, and more.
- Authors are selected for their expertise; you'll benefit from their balanced perspective on the topic and their wealth of clinical experience.
- Each article is extensively referenced, saving you hours of library research.

Stay at the forefront of your specialty! Subscribe today by returning the order form or by calling our toll-free number.

Yes! Please begin my subscription to ***Current Problems in Obstetrics, Gynecology and Fertility*** (6 issues per year).

What if we made CIN management safer, simpler, more cost effective and completely office based?

Think about this.
Your current choices in CIN management...laser, cold knife and cryosurgery, are either expensive or time consuming—or both. You may have to consider a possible general anesthetic. Also, is the treatment effective—is the biopsy adequate and how much follow-up is required. Wouldn't it be nice if the choices were simpler?

We thought you'd agree.
That's why Utah Medical developed the Prendiville Disposa-Loop™. A disposable electrosurgical loop designed specifically for complete management of CIN, HPV and other cervical dysplasias.

As a matter of fact
The research is showing that large loop excision of the transformation zone (LLETZ) is providing the best possible biopsies for histological examination. That's because specimens have clean and precise margins without the tissue damage created by laser technology. Also, research has shown that loop excisions are more likely to identify micro-

The Disposa-Loop is safer and more effective for your patient—easier for you—and more cost effective for both of you.

invasive disease. This means a more complete and successful treatment plan for your patient.

LLETZ also creates less patient discomfort, less bleeding and requires less follow up treatment. And when you consider that Disposa-Loop therapy is a 3 to 5 minute office procedure that requires only a local anesthetic, the choice becomes even clearer—the Disposa-Loop is more effective, simpler and more affordable for you and your patient.

Put it to the test
By now you may have received an invitation to attend our "Master Course"—Advanced Colposcopy and Modern Loop Management of CIN. Utah Medical, along with the California Medical Association, is co-sponsoring four C.M.E. accredited seminars on the Disposa-Loop. This will be your chance for "hands-on" practice—a chance to see that it really is as good as we say.

Take the next step
Call us, toll free, and talk with one of our Customer Service Representatives. We'd like to send you the research so you can see for yourself. Or, if you haven't received an invitation to the Master Course we'll make sure you get one. But do it today. Because the sooner you call, the sooner you'll have complete CIN management as part of your daily practice. **1-800-533-4984**

Impact of tubal sterilization and vasectomy on female marital sexuality: Results of a controlled longitudinal study

Rochelle N. Shain, PhD,[a] Warren B. Miller, MD[b] Alan E.C. Holden, MA,[a] and Marc Rosenthal, MD, PhD[a]

San Antonio, Texas, and Palo Alto, California

To determine if female or male sterilization affects long-term female marital sexuality, we prospectively compared baseline data and 5 consecutive years of follow-up data from 152 tubal sterilization women, 106 vasectomy wives, and 83 women not planning sterilization. By follow-up year 5, no group of women expressed any change in satisfaction with their own sexual response; however, all groups showed a significant decrease across time in satisfaction with their sexual relationship, in coital desire, and in coital frequency. There were no group differences in overall net changes or in rates of change over the 5-year period. However, two short-term group differences were noted: a decrease in coital desire among women not planning sterilization between baseline and follow-up year 4, compared with increases for both sterilization groups, and an increase in coital frequency at the first follow-up year only in the tubal sterilization group. These data indicate that there are no detrimental effects and some short-term benefits of both sterilization procedures on female marital sexuality. (AM J OBSTET GYNECOL 1991;164:763-71.)

Key words: Female marital sexuality, change in sexuality, tubal sterilization, vasectomy

Surgical sterilization has become the most common contraceptive method for currently or previously married women in the United States.[1] As of 1984 approximately 17,700,000 (8,050,000 male and 9,650,000 female) sterilizations had been performed in the United States.[2,3] Estimates are not available for 1985 or 1986. During 1987, however, the Association for Voluntary Surgical Contraception[4] estimates that an additional 640,000 female and 336,000 male procedures were performed; moreover, other sources[5] indicate that in 1987, 51% of married women who were neither pregnant, trying to conceive, nor infertile, and who were using contraception, were protected by male or female sterilization. The popularity of these procedures is not confined to the United States. International estimates made in 1982 and 1984 indicate that approximately 33 million couples are protected by vasectomy[6] and 95 million by tubal sterilization.[7]

Despite the worldwide popularity of female and male sterilization, there are large gaps in our knowledge regarding long-term psychosocial and physical sequelae.[8-14] Of particular interest is long-term change in female sexuality, primarily coital frequency, sexual desire, and sexual satisfaction. Deterioration in some aspect of sexuality after female sterilization is reported by 2% to 28% of women, whereas improvements range between 0% and 55%.[10,12] In most studies the majority of respondents report no change or improvements.[10,12] Both positive and negative changes have been reported within the same study, as might be expected, because sterilization can have different psychological effects on different people. For example, positive effects may result from liberation from fears of pregnancy and negative effects from associating desirability with reproductive integrity.

Several studies compared sterilized women with users of nonpermanent contraceptive methods or with women married to vasectomized men. In a prospective British study, women who had undergone tubal sterilization showed greater improvement in overall sexual relationships than did users of nonpermanent methods at 1 year after the procedure. The latter, in fact, reported less satisfaction than they reported in baseline interviews.[15] Two retrospective investigations at 6 months'[16] and 2 years'[17] follow-up suggested that wives of vasectomized men showed greater increases in sexual desire[16] and had higher rates of coital frequency[17] and fewer sexual problems[17] than did sterilized women.

A few studies considered sexual change at more than one time point after sterilization. In a prospective, but uncontrolled British investigation,[18] women who had tubal sterilization experienced an increase in coital frequency at 6 months after the procedure that disappeared by 18 months. Married women included in both

the 1970 and 1975 National Fertility Studies, who were initially sterilized or who became sterilized during the interval, experienced smaller (statistical significance is not addressed) declines in coital frequency than did users of other methods, including vasectomy.[19]

Whereas prior studies have made valuable contributions, results are inconsistent and do not allow rigorous assessment of sterilization's impact on sexuality, especially as it changes over time. Limitations include retrospective design, subjective assessment of change, short follow-up periods, very small sample size, examination of limited aspects of sexual behavior, lack of independent controls, and/or failure to control for factors that may independently affect sexuality.

This article compares changes in coital frequency, coital desire, and satisfaction with sexual relationship and personal sexual response across 5 years of follow-up among sterilized women, women married to vasectomized men, and women who had completed childbearing but did not plan sterilization. These groups are subsequently referred to as tubal sterilization women, vasectomy wives, and women not planning sterilization. On the basis of the literature, we hypothesized that female sterilization and vasectomy would have no effect, or perhaps a small positive effect, on sexuality.

Material and methods

Sample selection. Subjects are non-Hispanic, white women between 19 and 49 years of age, chosen from patients in approximately 50 obstetrics and gynecology and urology offices and clinics in San Antonio, serving lower-, middle-, and upper-class individuals. All protocols received institutional review board approval. Women in the tubal sterilization group were recruited through a letter given to them in their physicians' offices. Space was provided for names and telephone numbers of patients who agreed to be contacted. Women who did not permit further contact were requested to provide (anonymously) basic sociodemographic information. Women accompanying their husbands to urology offices for preoperative vasectomy counseling or inquiries were also given recruitment letters. Men who were not accompanied by spouses were asked to release their wives' names and phone numbers. Trained interviewers followed up with telephone contact, at which time additional information about the study was provided and an interview was scheduled. Women who reported that tubal sterilization or vasectomy was being performed solely because of the wife's medical status were excluded.

Women not planning sterilization were recruited in various ways, primarily through distribution of recruitment letters, recruitment in physicians' offices by study personnel, and physician-staff searches of patient files (according to alphabetic listings determined by random selection procedures), followed by telephone contact. Post hoc statistical analyses demonstrated that different recruitment methods did not result in different sample characteristics.

Analyses are based on data from women married continuously to the same partner. The initial study sample consisted of 728 participants (the refusal rate was 10.9%); 621 of these were married. Attrition between the initial and fifth follow-up years among married respondents was 12% (547 women). We excluded 117 who changed marital status, 61 who changed study group status (primarily switching from not planning sterilization to undergoing sterilization), 26 who underwent a hysterectomy, and 2 who did not respond to sexuality questions. The resultant sample consisted of 341 women: 152 women in the tubal sterilization group, 106 in the vasectomy wives group, and 83 in the not-planning-sterilization group.

Interview procedures. Baseline information (initial interview) was collected from tubal sterilization women and vasectomy wives immediately before sterilization and from women not planning sterilization soon after recruitment. The interview preceded sterilization by several months for a small minority of women who postponed the procedure. Follow-up interviews were conducted for 5 years at yearly intervals from the first interview date (December 1980 to March 1982). All women were interviewed in locations of their choosing during the initial year and the first 2 years of follow-up. The remaining interviews were conducted by telephone. A reliability check demonstrated that only 4% (13 of 350) of repeat menstrual and psychosocial responses, obtained several days to 1 month after the initial interview, differed from the original.

Measures of sexuality. Mean satisfaction with sexual relationship with husband was measured on a 7-point scale from very low (1) to very high (7). Satisfaction with one's own sexual response was measured on a 4-point scale ranging from not satisfied (1) to very satisfied (4). Average annual frequency of coital desire and coital frequency were obtained by asking women to choose one of the following responses: several times a day (converted to 730 episodes), every day (converted to 365), a few times a week (converted to 182), once a week (converted to 52), a few times a month (converted to 26), once a month (converted to 12), a few times a year (converted to 6), and never (converted to 0). Respondents were more comfortable and thus possibly more forthright in their reporting, selecting from response options than providing an "exact" number. Our nonresponse rate, $<1\%$, was much lower than the 5.3% to 8.3% reported in the National Fertility Studies.[19] We chose an average over the past 12 months as opposed to a shorter interval, e.g., the previous month, because coital frequency often varies. Moreover, since a consid-

erable minority of subjects were 9 months pregnant when interviewed initially, their current data would not have been meaningful. Pregnant women were asked to provide their average frequency before pregnancy. Our aim was not to produce precise frequencies but to examine change through time. Consequently, whereas our annual tallies may not be entirely accurate, there is no reason to question the direction or magnitude of change.

Data analysis. Since a wide variety of factors may influence sexuality, we first examined a correlation matrix associating the four dependent variables at baseline with approximately 70 independent variables, drawn from the following areas: (1) demographic characteristics of respondents and spouses (e.g., age, educational level, Duncan's Socioeconomic Status (SES) scale ratings,[20] religion, employment status, income, and length of marriage); (2) feelings about oneself (e.g., self-confidence, satisfaction with femininity, hopefulness); (3) feelings about one's marriage (e.g., conflict level with spouse, satisfaction with marriage, stability of marriage); (4) pregnancy status; (5) type of contraception used; (6) overall physical health; (7) desire for more children; and (8) Spielberger Trait Anxiety scores.[21] All variables that were significantly related to any of the dependent measures were tested for differences among groups with χ^2 or analyses of variance. The Student–Newman-Keuls test was used to determine which groups differed for those variables for which an overall significant effect was found. Our objective was to identify independent variables that might account for group differences in sexuality. Consequently, only those variables that were significantly or close to significantly ($p < 0.1$) different among groups were included in stepwise (backward and forward) multiple regression analyses with the four sexuality measures as dependent variables.

To simplify and improve the explanatory power of our models and avoid potential problems of colinearity among predictor variables, related items were combined into factors (α-factor extraction, no rotation) for possible use as covariates. Factor scores for each case were computed with the use of factor-score coefficients for each variable, and group differences were ascertained with analysis of variance. We chose as covariates the set of factors and individual variables that differed between groups ($p \leq 0.05$) and accounted for the largest amount of variance in the dependent variable.

The selected covariates were used in a repeated-measures analysis of covariance to determine cross-sectional group differences, i.e., in baseline and overall average (average group effect, considered over all time points) values for each dependent variable. Adjusted means were computed from the inverse of the transformation matrix used in the repeated-measures analysis of covariance. An overall time effect and group differences in rates of change (comparison of slopes) were determined with the use of repeated-measures analysis of variance over the six time points. Changes between pairs of succeeding years and between baseline and each follow-up year were determined with the use of analysis of variance. Overall net change, i.e., the difference between baseline and follow-up year 5 values, was determined through analysis of covariance, with the use of baseline values for pertinent sociodemographic covariates. Power of these analyses ranged between 0.81 and 0.89.

Results

Sociodemographic and psychosocial characteristics of sample. Several sociodemographic differences were noted among the three groups (Table I). Women not planning sterilization were the oldest, were married the longest, were the best educated, and had the highest Duncan's SES scale rating. Their husbands were also the oldest and the best educated. Husbands of vasectomy wives had the lowest income; the combined household income of this group was also the lowest.

All three groups were similar in trait anxiety levels and in the following psychosocial characteristics: evaluation of general happiness, number of personal problems, evaluation of one's own mental health, self-confidence, satisfaction with one's physical attractiveness, satisfaction with division of labor at home, conflict level with husband, effectiveness of marital conflict resolution, evaluation of which spouse acquiesces more in conflict situations, interest in another baby, and involvement with religious activities. Vasectomy wives, however, were most hopeful about the future ($p < 0.02$) and most certain of the stability of their marriage ($p = 0.01$); tubal sterilization women were least satisfied with their role as mother ($p = 0.01$). Differences in satisfaction with marriage and with femininity approached statistical significance, with vasectomy wives being most positive. The two psychosocial factors incorporating these variables (see Table II) varied significantly among groups, with vasectomy wives more positive than tubal sterilization women. All sociodemographic and psychosocial variables were examined for potentially confounding effects on the dependent variables and were controlled for when indicated.

Independent variables related to sexuality. Various age-time, sociodemographic, and psychosocial variables were significantly associated with one or more of the sexuality variables. In general, age, marital duration, educational level, Duncan's SES scale rating, income, and trait anxiety had negative associations. The following psychosocial variables were associated with higher levels of sexual satisfaction and/or activity: positive evaluation of general happiness, hopefulness regarding the future, positive evaluation of one's own mental

*Means are presented as both observed and adjusted (for effects of significant covariates) values. Covariates include woman's education, years married, and psychosocial factor 1 (R^2 = 0.321, p = 0.000). p Values are based on the F statistic for means.

†Scale ranges from 1 (very low) to 7 (very high).

‡Refers to group differences in baseline values, in changes between succeeding years, or in changes between baseline and each follow-up year. In cases of significant differences the specific comparison is indicated in a footnote.

fect) over the 5-year period (without adjustments, vasectomy wives were significantly [p = 0.02] more satisfied over 5 years than were women not planning sterilization). There was, however, an overall time effect: all groups decreased significantly (an average of 0.31 or 5.5%), moving from the category "high" toward "mostly high." There were no significant group differences in rate of change, overall net change, or changes between any two given years.

Satisfaction with one's own sexual response. As shown in Table IV, satisfaction with one's own sexual response did not change significantly through time. With or without covariates, there was no significant group effect on mean values; throughout the study all groups remained between moderately and very satisfied (but closer to the moderate category) with their sexual response. There were no significant group differences in rate of change, overall net change, or changes between any two given years.

Frequency of coital desire. There were no significant group differences (see Table V) in adjusted values for coital desire at baseline or averaged over the 5-year period (without adjustments, women not planning sterilization had significantly [$p < 0.04$] lower average frequencies than did either sterilization group). There was, however, an overall time effect: all groups had a significant decrease (an average of 15.3 coital episodes or 11.5%). There were no group differences in rate of change or in overall net change. Duration of marriage was negatively related ($p < 0.02$) to net decrease in desire: Women married the shortest time at baseline showed the largest declines during the 5-year period.

Although there were no group differences in overall net change, there was a difference in pattern of change. Follow-up values for both sterilization groups were higher than initial values until the fifth follow-up year, at which time they dropped below baseline levels. Among tubal sterilization women, coital desire peaked at the first follow-up year. However, the relatively large increase was not significantly different from the slight increase shown by vasectomy wives or the slight decrease shown by women not planning sterilization. Wives of vasectomized men showed a steady increase in desire, peaking at follow-up year 3. Women not planning sterilization, on the other hand, exhibited an immediate decline, with the largest drop at follow-up year 4. At this time the net change experienced by both sterilization groups (an increase) was significantly (p = 0.03) different from that of women not planning sterilization (a decrease). However, by follow-up year 5, when all groups showed a decline, the overall net change, although larger for women not planning sterilization, was not significantly different.

Coital frequency. There were no significant group differences (see Table VI) in adjusted values for coital frequency at baseline or averaged over the 5-year period (without adjustments, women not planning sterilization had significantly lower [$p < 0.03$] average frequencies than did either sterilization group). The difference made by covariates is seen clearly in Fig. 1, where observed and adjusted coital frequency values are compared graphically. Without covariates there is a clear difference between the sterilization groups and women not planning sterilization. With covariates, the time lines are close to one another.

There was an overall effect of time: All groups had a significant decline (an average of 19.7 episodes or 14.4%); there were no group differences in rate of

§Changes (between baseline and fourth follow-up year) experienced by tubal sterilization women and vasectomy wives (increases) are different from change experienced by women not planning sterilization (decrease).

change or in overall net change. By follow-up year 5, women who had undergone tubal sterilization showed the smallest (although not significantly different) net decline. As in the case of coital desire, duration of marriage had a significant impact on net decline, with women married the shortest time showing the largest drop ($p < 0.01$).

Although there were no long-term group differences, tubal sterilization women showed a significant increase in coital frequency at first-year follow-up, compared with both vasectomy wives (slight decrease) and women not planning sterilization (large decrease). The following year they experienced a significant decrease, bringing them back in line with the rest of the sample. After this point their pattern was similar to that of the other groups, i.e., an overall decline.

Despite their increase in both coital desire (not significant) and coital frequency, tubal sterilization women were not initiating intercourse more frequently than they had during the preceding year; nor were there changes in husband-wife patterns regarding which partner desired intercourse more often. In both years

†Scale ranges from never to several times a day.

‡Refers to group differences in baseline values, in changes between succeeding years, or in changes between baseline and each follow-up year. In cases of significant differences, the specific comparison is indicated in a footnote.

§Change (between baseline and first-year follow-up) experienced by tubal sterilization women (increase) is different from that experienced by women not planning sterilization and vasectomy wives (decreases).

‖Change (between first and second follow-up years) experienced by tubal sterilization women (decrease) is different from that experienced by women not planning sterilization and vasectomy wives (slight increases).

tubal sterilization women perceived that sexual activity either was initiated equally by both partners (53% in both years) or was always or usually initiated by the husband (43% at baseline, 44% at follow-up year 1). Again, in both years they perceived either that there were no spousal differences in coital desire (40% and 42%) or that their husbands desired it more often (53% and 50%). There were no group differences in either of these variables with respect to mean values or change through time.

The experience of a coital frequency increase by tubal sterilization women and not by vasectomy wives was not readily interpretable. At first-year follow-up respondents in both groups were asked if they had feared pregnancy before sterilization and how they currently felt. Approximately 45% of tubal sterilization women and 54% of vasectomy wives initially feared pregnancy; 96% of the former group and 91% of the latter group were no longer afraid. There were no group differences either in initial fear of pregnancy or in the subsequent relief of that fear. Given the absence of a straightforward explanation, we are conducting further analyses, which will be published later.

Comment

Examination of sexual change during a 5-year period indicated (1) overall declines in satisfaction with sexual relationship, in coital desire, and in coital frequency; (2) confounding negative effects of age, marital duration, income, education, and occupational SES and positive effects of psychosocial factors (related to satisfaction with marriage and oneself) on cross-sectional measures of sexuality; and (3) an inverse relationship between marital duration and overall net decline in coital desire and frequency. These findings are consistent with those reported in the literature.

Decrease in marital coital frequency through time is well documented. Although some controversy exists, it appears to be primarily a function of marital duration, age of the male partner, and/or age of the female partner.[19, 22-26] Whereas coital frequency decreases as marital duration increases (probably because of reduced novelty, decreased energy levels, and increased time commitments to children and career), declines for individuals studied at different time points indicate the sharpest drops occur in the earlier years of marriage, presumably when reduced novelty has its greatest impact.[23, 24] The positive relationship between sexuality and general marital adjustment and the dampening effect of higher educational attainment on couple sexuality have also been previously reported.[16, 23, 26] The former relationship makes good theoretical sense but the latter requires some explanation. It is theorized that couples with higher incomes (and presumably higher educational attainment) have greater access to leisure-time alternatives to sexual activity.[23] They may also be employed in more demanding, high-stress positions and thus have less leisure time and less physical and psychic energy for sexual activity.

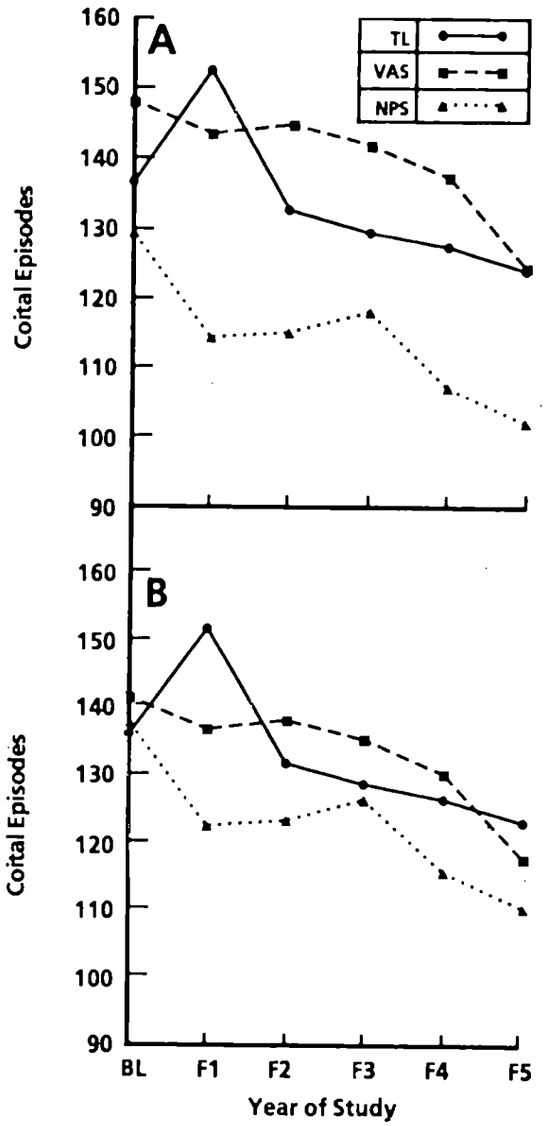

Fig. 1. A, Observed number of annual coital episodes among tubal sterilization women (*TL*, $n = 152$), vasectomy wives (*VAS*, $n = 106$), and women not planning sterilization (*NPS*, $n = 83$). **B,** Adjusted number of annual coital episodes among tubal sterilization women (*TL*, $n = 152$), vasectomy wives (*VAS*, $n = 106$), and women not planning sterilization (*NPS*, $n = 83$).

Change in satisfaction with one's own sexual response has not been previously addressed. However, its remarkable stability over time makes sense in that it reflects an internal state and is less influenced by external circumstances.

Our major concern was the long-term impact of male and female sterilization on female marital sexuality. Our data demonstrate an overall absence of group differences in four dimensions of sexuality considered over a 5-year period. No long-term effects of either type of sterilization were noted. Group differences in observed average values were a function of differences in sociodemographic and psychosocial characteristics. Once these effects were removed, group differences disappeared.

The two short-term group differences noted were a decrease in coital desire among women not planning sterilization between baseline and the fourth follow-up year, compared with increases experienced by both sterilization groups and an increase in coital frequency at the first follow-up year only in tubal sterilization women. The latter change is similar to that observed by Cooper et al.[18]

The increase in coital desire among sterilization groups appears related to the sterilization procedures and the freedom from fear of pregnancy they confer. These data suggest that sterilization may act as a short-term buffer against the natural tendency for aging and increasing marital duration to depress sexual desire.

The explanation for the temporary coital frequency increase in the tubal sterilization group alone is less apparent. Freedom from pregnancy fears, while certainly related to increased coital frequency, does not account for this difference. Tubal sterilization women were not more fearful of pregnancy than were vasectomy wives; nor were they more often relieved afterward. We are conducting detailed analyses to investigate this phenomenon. In the interim we speculate that taking charge of one's *own* reproduction may elicit positive feelings about oneself and foster the ultimate purpose of non–medically indicated sterilization—worry-free coital activity. Moreover, a woman who takes it on herself to be sterilized may want (consciously or not) to realize immediate benefit.

However, increased coital activity was not effected by more frequent female initiation of sexual activity or by a change in husband-wife patterns regarding which partner desired intercourse more often. Overall, as perceived by women, men remained more desirous and the more usual initiators of sexual intercourse. Perhaps women who had undergone tubal sterilization became more receptive to coital activity than they had been in the past and somehow communicated their heightened desire, a behavior they may not have considered outright initiation.

These data provide some assurance, within the limitations of our sample, regarding the short- and long-term sexual consequences of non–medically indicated tubal sterilization and vasectomy. There appear to be no detrimental effects and some short-term benefits of both procedures on female marital sexuality.

We are indebted to Drs. Sondra T. Perdue and Gary M. Clark for help with statistical analysis and to Dr. Carl J. Pauerstein for his thoughtful review of this manuscript.

The "Allis" test for easy cesarean delivery

Michael A. Finan, MD, Dimitrios S. Mastrogiannis, MD, PhD, and William N. Spellacy, MD
Tampa, Florida

Cesarean delivery may be complicated by dystocia if the incision size is inadequate. A test is described that may be easily applied at cesarean section, creating greater objectivity in the determination of surgical incision size. One hundred patients were studied prospectively. Patients with incisions that passed the test had a shorter mean time of delivery and less difficult deliveries than those of patients with incisions that failed the test. We conclude that the "Allis" test is a simple way to reduce the incidence of dystocia at cesarean delivery. (AM J OBSTET GYNECOL 1991;164:772-5.)

Key words: Test, cesarean section, dystocia

Cesarean section is the most common major surgical procedure in the field of obstetrics and gynecology.[1] Cosmetic considerations may exert pressure on the surgeon to produce incisions that are small, and thus less disfiguring. However, smaller incisions often restrict exposure of the operative field and may increase the difficulty of delivery.

In 1987 Ayers and Morley[2] determined that an abdominal incision size ≥15 cm is associated with significantly less difficulty in cesarean delivery. Their efforts stimulated interest in the development of an efficient and simple way to test the wound size and thus reduce the incidence of difficulty at cesarean delivery. The purpose of this study was to develop a test that would predict easy cesarean delivery and thus reduce dystocia and speed delivery at cesarean section.

The test proposed is to use a common instrument, the Allis forceps, as a wound size gauge. This forcep measures approximately 15 cm in length and is readily available.

Material and methods

Between Jan. 1 and April 30, 1990, 100 patients undergoing cesarean section at Tampa General Hospital were prospectively entered in the study.

The surgery was performed by the resident staff and the attending physicians. A vertical or Pfannenstiel skin incision was performed. After entering the peritoneal cavity, two Richardson retractors were used to retract the abdominal walls laterally. An Allis clamp was then held between the retractors. The test was described as "passed" if the clamp easily fit between the retractors and "failed" if the clamp was longer than the distance between the retractors, as in Fig. 1. The cesarean delivery was undertaken in the usual fashion,[3,4] regardless of the outcome of the test. All the uterine incisions were of the low-transverse type. To objectively assess difficulty of delivery a circulating nurse recorded the length of time in seconds between the start of the uterine incision, after the bladder was removed from the lower segment, and delivery of the fetus. The operators subjectively graded the difficulty of delivery with a scale of I to IV as follows: I = no dystocia, very easy delivery; II = moderate effort required to effect delivery; III = forceful abdominal pressure required for delivery; IV = extension of the incision or muscle splitting was required for delivery.

Obstetric and epidemiologic data were obtained from the medical records of these patients. The results were analyzed statistically with the Student's t test and χ^2 test where appropriate. The analysis was performed with the assistance of the SPSS statistical computer package. A p value of <0.05 was considered significant.

Results

Of the 100 patients entered in the study, 39 incisions passed the "Allis" test and 61 incisions failed the test. The patients were similar with regard to type of skin incision, type of anesthesia, presentation, and sex of the fetus, as shown in Table I. Sixty-eight (68%) of the patients had a fetus in the vertex presentation and 32 (32%) were breech. In the group with incisions that passed the test, 24 (61%) were vertex and 15 (39%) were breech. In the group with incisions that failed the test, 44 (72%) were vertex and 17 (28%) were breech. These differences were not statistically significant. A total of 85% of the skin incisions were Pfannenstiel and 15% were vertical. The majority of cesarean sections were primary (76%) with 24% being repeat cesarean sections. Of the group with incisions that passed the test, 28 (72%) underwent primary and 11 (28%) underwent repeat cesarean sections. Of the group with incisions that failed the test, 48 (79%) were primary and 13 (21%) were repeat cesarean sections. These differences were not statistically significant.

The group with incisions that passed the "Allis" test had a higher mean age and parity than those of the group with incisions that failed the test. The groups were similar with regard to gestational age, birth weight, and cord pH as shown in Table II.

The patients with incisions that passed the test had a shorter length of time from uterine incision to delivery than that of those with incisions that failed the test. The mean time of delivery was 58.4 seconds (range, 15 to 190) for those with incisions that passed the test and 95.7 seconds (range, 30 to 270) for those with incisions that failed the test ($p < 0.005$).

The group with incisions that passed the test had a statistically significant difference ($p < 0.05$) between the 1-minute Apgar scores for each grade of dystocia. In the group with incisions that failed the test, we found no difference between the 1-minute Apgar scores and the four grades of dystocia (see Table III). Comparison of the Apgar scores for every grade of dystocia within each of the two groups (passed and failed) did not show a statistically significant difference.

Fig. 2 shows the percentage of patients in each group (passed versus failed) with a particular grade of dystocia. A total of 26.3% of patients with incisions that failed the test had a grade III or IV delivery, whereas

only 7.7% of those with incisions that passed the test had a delivery of this difficulty ($p < 0.05$).

Comment

The tendency of surgeons to create smaller incisions for cosmetic reasons is understandable. *Williams' Obstetrics*[4] states that the cesarean section incision should be of sufficient length to permit delivery of the infant without difficulty. Ayers and Morley[2] determined that difficult deliveries, in which forceful pressure on the maternal abdomen was required to effect delivery or in which enlargement of the incision was required for delivery of the infant, were related to an incision size <15 cm. The same study suggested that the degree of difficulty during delivery of the fetus correlates inversely with incision size.

The present study evaluated prospectively a test that would predict easier, more rapid delivery at cesarean section. The groups were similar with regard to birth weight, gestational age, and cord pH. The fact that the group with incisions that passed the "Allis" test had a higher mean age and parity than those of the group

with incisions that failed the test could be explained because of more relaxed abdominal walls in this group.[5]

The group with incisions that passed the "Allis" test who were delivered of infants with grades I and II dystocia had significantly higher 1-minute Apgar scores than those with grades III and IV dystocia ($p < 0.05$). This difference was not found for the group with incisions that failed the test. Comparison of 1-minute Apgar scores of the two groups (passed versus failed) shows there was no statistically significant difference. There was also no difference within each group or between the groups in the 5-minute Apgar scores. These differences may be elicited with larger numbers in each group.

The failed "Allis" test was associated with a longer delivery time and a significantly more difficult delivery than was the passed "Allis" test.

Factors that affect difficulty of cesarean delivery are varied. They include parity, abdominal wall relaxation, station, position of the presenting part, and size of surgical incision. One of the factors that we can control to reduce the incidence of dystocia at cesarean delivery is the size of the surgical incision. We conclude that application of the "Allis" test is an objective way to control the size of surgical incision at cesarean delivery.

The Allis clamp measures approximately 15 cm and is readily available. If the instrument fits between two retractors that distend the abdominal incision laterally, the delivery can be carried out easily.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Flow velocity waveforms of the fetal circulation preceding fetal death in a case of lupus anticoagulant

Giancarlo Mari, MD,[a] and Nathan Wasserstrum, PhD, MD[a, b]
Houston, Texas

Flow velocity waveforms of the vascular system were evaluated at 25 weeks 2 days and 27 weeks 5 days of gestation in the case of a severely growth-retarded fetus. At the first scan, the cerebral vessels displayed low pulsatility indexes, reflecting the brain-sparing pattern that characterizes fetal stress. This compensatory reduction was lost at the time of the second, "preterminal" scan. (AM J OBSTET GYNECOL 1991;164:776-8.)

Key words: Brain-sparing effect, fetal Doppler, intrauterine growth retardation, pulsatility index

Flow velocity waveforms of the umbilical artery, middle cerebral artery, and other vessels have been described in normal fetuses. Characteristic changes in the waveforms have been reported in association with chronic fetal stress and growth retardation.[1] The changes that the latter pattern may undergo as a reflection of preterminal decompensation in the last hours or days before intrauterine death have not yet been defined. We assessed the Doppler flow velocity waveforms of various fetal arteries, the ductus arteriosus, and the semilunar valves in a growth-retarded fetus. The pregnancy was complicated by antiphospholipid syndrome (lupus anticoagulant). Doppler studies were performed at 25 weeks 2 days and again at 27 weeks 5 days of gestation. The fetus died in utero within 24 hours of the second scan. Hence we were able to characterize the various Doppler flow velocity waveforms within 24 hours of fetal death.

Case report

Routine first-trimester laboratory evaluation of a 32-year-old Oriental woman, gravida 1, para 0, revealed a positive reactive plasma reagin test. Fluorescent treponemal antibody test results were negative. Pertinent results of further evaluation included an elevated partial thromboplastin time of 51 seconds, a normal prothrombin time of 11.5 seconds, a positive lupus anticoagulant battery, anticardiolipin antibodies (enzyme-linked immunosorbent assay) that were positive for immunoglobulin G (>6 multiples of the mean) and strongly positive for immunoglobulin M (>12 multiples of the mean), and an anti–deoxyribonucleic acid antibody titer >1:320. There was no history of thrombotic events or systemic lupus erythematosus.

At 17 weeks' gestational age, a diagnosis of antiphospholipid syndrome (lupus anticoagulant) was made and the patient was started on a regimen of low-dose aspirin (80 mg twice per day). Ultrasonographic measurements at this time were consistent with menstrual age. A repeat ultrasonogram at 25 weeks yielded an estimated fetal weight of 430 gm, head circumference of 19.5 cm, and abdominal circumference of 14.3 cm. The patient was hospitalized with a diagnosis of fetal growth retardation associated with antiphospholipid syndrome.

Biophysical evaluation revealed normal fetal breathing and body movements and tone. Amniotic fluid volume was subjectively somewhat decreased. Amniocentesis revealed no chromosomal abnormalities. Prednisone (20 mg per day) and supplemental oxygen were added to the patient's regimen.

At 25 weeks 2 days, after informed consent was obtained from the patient and with the consent of her attending obstetricians, we evaluated fetal vascular flow patterns via Doppler ultrasonography. The results were made available to the patient's obstetricians. At 27 weeks 5 days ultrasonography showed no fetal breathing or body movements and moderately decreased amniotic fluid. We performed a repeat Doppler evaluation. The following day, fetal cardiac activity was absent. Labor was induced and a male infant weighing 430 gm, with Apgar scores of 0 at both 1 and 5 minutes, was delivered vaginally.

Doppler studies were performed with a General Electric PASS II dynamic image scanner. The pulsatility index was calculated as the difference of peak systolic velocity minus lowest diastolic velocity, divided by mean velocity. At the first Doppler evaluation, performed at 25 weeks 2 days the pulsatility index values of the fetal middle cerebral artery (Fig. 1), internal carotid artery, and anterior cerebral artery (Table I) were all abnor-

Renal artery	—	—	4.50	2.0-3.8
Iliac common artery	—	—	3.90	—
Peak systolic velocity				
Ductus arteriosus (cm/sec)	70	—	65	—
Pulmonary valve (cm/sec)	55	—	60	—
Aortic valve (cm/sec)	60	—	60	—
Tricuspid valve	No tricuspid insufficiency		No tricuspid insufficiency	

mally low, reflecting reduced impedance to cerebral blood flow. Diastolic velocity was absent in the umbilical artery and in the abdominal aorta (Table I). There was no evidence of constriction of the ductus arteriosus or associated tricuspid insufficiency. Peak systolic velocities at the pulmonary and aortic valves were normal. Fetal heart rate at the time of Doppler measurements was 160 beats/min.

At the second Doppler evaluation performed at 27 weeks 5 days the pulsatility index values of the middle cerebral artery (Fig. 1), internal carotid artery, and anterior cerebral artery all had risen (Table I) to the normal range, i.e., the range expected in a normal, nonstressed fetus. Diastolic velocity was reversed in the umbilical artery (Fig. 1), the thoracic and abdominal aorta, and the internal iliac artery and was absent in the renal artery (Table I). Peak systolic velocities of the ductus arteriosus, and the pulmonary and aortic valves were unchanged from the preceding examination (Table I). Fetal heart rate was 150 beats/min.

Comment

Severe growth retardation at 25 weeks 2 days of gestation, in the context of the antiphospholipid syndrome, reflects chronic fetal stress. Absence of the Doppler flow velocity waveforms of the umbilical artery and abdominal aorta, further support the diagnosis of fetal hypoxemia. Of interest, routine biophysical index values of fetal status (breathing and body movements and tone) were still normal at this time, despite markedly abnormal Doppler waveforms.

On repeat evaluation 2 weeks later, the umbilical artery and aortic waveforms showed further deterioration, with higher pulsatility index and the appearance of reversed flow. Abnormal diastolic velocity patterns also were noted in vessels not examined at the earlier examination, i.e., the renal and common iliac arteries and the thoracic aorta.

At the time of the first scan the pulsatility index values of all three cerebral arteries were "abnormally" low,

i.e., below values expected in the normal fetus. These "abnormalities" presumably reflected a brain-sparing effect that characterizes chronic fetal hypoxia, i.e., an appropriate compensatory decrease in cerebrovascular impedance and a redistribution of blood flow in favor of the brain. These studies are consistent with studies in the acutely hypoxemic fetal lamb, which have directly demonstrated such a redistribution of flow. Of special note, this brain-sparing effect was no longer present at the time of the second scan, shortly before intrauterine fetal death. We speculate that these changes could indicate extremely severe fetal compromise and a reduction in cerebral blood flow. These results would be in agreement with those observed in fetal sheep, in which a reduction in cerebral blood flow has been observed during sustained hypoxemia and acidemia.[2] Under these circumstances, concomitant reduction of renal blood flow occurs. Loss of brain-sparing effect with persistent absent or reversed diastolic flow of the umbilical artery raises concern about particularly severely compromised fetal status, possibly signaling imminent fetal death.

We thank Laura J. Bryson for helpful comments on the manuscript.

Recurrent herpes gestationis with postpartum flare: A case report

Laxmi V. Baxi, MD, Oormila P. Kovilam, MD, Margaret H. Collins, MD, and Robert R. Walther, MD

New York, New York

A case of herpes gestationis recurring in each pregnancy, with a postpartum flare-up in the last pregnancy, is described. The diagnosis was confirmed by skin biopsy. The first pregnancy ended in a term stillbirth, but there were favorable outcomes in four subsequent pregnancies. Histopathologic examination of the placentas of the last three pregnancies revealed varying grades of villositis. Symptoms improved with oral corticosteroids. (AM J OBSTET GYNECOL 1991;164:778-80.)

Key words: Herpes gestationis, autoimmune disorder in pregnancy

Herpes gestationis is a rare skin disorder, which is peculiar to pregnancy and the postpartum period and is characterized by vesiculobullous lesions. This disorder presents a diagnostic challenge and needs close monitoring to reduce maternal and fetal morbidity.

Case report

In a 31-year-old woman (gravida 6, para 4) progressively increasing pruritus developed on the trunk and extremities beginning in the third trimester. These symptoms and signs responded minimally to oral antihistamines and a topical hydrocortisone cream. In the current pregnancy fetal well-being was assured by nonstress tests starting at 36 weeks' gestation. At 38 weeks the patient was delivered of a female infant weighing 3000 gm with Apgar scores of 9 and 9. On the second postpartum day a bullous lesion developed on the plantar aspect of the left foot (Fig. 1), followed 4 weeks post partum by flare-up of the disease with vesiculobullous lesions (Fig. 2). She responded to 30 mg of oral prednisone that was gradually tapered. The diagnosis

Fig. 1. Dermatologic lesions of foot and leg in herpes gestationis.

Fig. 2. Dermatologic lesions of hand and arm in herpes gestationis.

of herpes gestationis was confirmed by skin biopsy, which revealed a subepidermal blister with perivascular infiltrate of eosinophils. The patient was a known case of recurrent herpes gestationis in which the diagnosis was confirmed by skin biopsy in the first pregnancy. Her history was significant for vesiculobullous lesions in all her previous viable pregnancies. In each pregnancy the onset of the disease was later and the severity was lessened. She required 120 mg/day oral prednisone in the first two viable pregnancies and 30 mg/day in subsequent pregnancies. The first pregnancy ended in a term stillbirth, allegedly the result of a cord accident.

Studies of the immune system of this patient in her first pregnancy were reported by Bonagura et al.[1] in *Human Immunology*. High titers of anti-HLA antibodies were detected then. Histolopathologic examination of the placenta in the last three pregnancies, while the patient was under our care, revealed varying degrees of villositis, with villi infiltrated with lymphocytes, plasma cells, and histiocytes.

Comment

The incidence of herpes gestationis varies from 1 in 4000 to 1 in 50,000, with a lower incidence when confirmed by immunofluorescence studies.[2] Recurrence in subsequent pregnancies is common and largely expected; however, postpartum onset of the disease is less common (14.63%).[2] Recurrence of the disease and postpartum flare-up, as in this patient, may indicate persistence of circulating autoantibodies. Flare-up of the disease also has been reported with establishment of menstruation in the postpartum period and with the use of oral contraceptives.

Although a significant increase in fetal morbidity has been reported in patients with herpes gestationis,[3, 4] such an association is questioned by others.[2] Shornick[2] attributed this disparity to the fact that the study of Lawley et al.[3] was based on literature review; hence it was more likely to include patients with more complicated disease and consequently poor fetal outcome.

Shornick's cases (no cases of adverse fetal outcome) were collected from immunofluorescence laboratory results, therefore possibly with less likelihood of selection bias. In the series of Holmes and Black[4] there was a wide referral base and all cases were included, creating a fair representation of fetal morbidity. In the patient described here, the first pregnancy ended in a term stillbirth. In subsequent pregnancies she underwent close observation, including antepartum fetal monitoring, and she received prednisone. Furthermore, analysis of the time of onset of lesions, severity of disease, placental pathologic condition, and fetal outcome in this patient showed that smaller babies occurred in the pregnancies in which placentas were severely affected. Evidence of villositis with lymphohistiocytic infiltration in the placenta, despite the absence of characteristic skin lesions in the antepartum period, shows that placental lesions may precede skin lesions.

Transvaginal color Doppler imaging in the assessment of uteroplacental blood flow in the normal first-trimester pregnancy

Richard Jaffe, MD, and Steven L. Warsof, MD

Chicago, Illinois

Characteristic changes of low resistance and high diastolic blood flow velocity were identified by Doppler studies starting in the early phase of the second trimester. These changes were attributed by some authors to trophoblastic invasion of the uterine vasculature converting the uterus into a low-resistance organ. Because of technical limitations previous studies were confined to the uterine artery and its main branches. With the development of color Doppler and transvaginal ultrasonography we can now identify blood flow in various small vessels in the placental bed. This study was performed to assess the ability of color Doppler ultrasonography to evaluate subtrophoblastic blood flow by color identification in the early phase of normal pregnancy from 5 to 9 weeks' gestation. Results show that the characteristic increase in diastolic blood flow is evident as early as 5 weeks' gestation. (Am J Obstet Gynecol 1991;164:781-5.)

Key words: Color Doppler ultrasonography, transvaginal ultrasonography, uteroplacental blood flow

The introduction of Doppler technology into obstetrics gave us the opportunity for noninvasive evaluation of uteroplacental and fetal circulation in both normal and abnormal pregnancies.[1-8] The association between abnormal Doppler studies and both maternal and fetal disease has been suggested by several authors.[9-14] Doppler studies of uterine and umbilical arteries in normal pregnancies showed a progressive increase in diastolic blood flow starting early in the second-trimester.[2, 5, 6, 9, 10, 15] This reflects a fall in peripheral resistance postulated to be caused by the trophoblastic invasion of the uterine vasculature converting the uterus into a low-impedance organ.[16] With the recent introduction of high-frequency vaginal probes with color Doppler imaging, blood flow within the smallest arteries around the trophoblast can be detected and studied. This prospective study was undertaken to assess blood flow within the smallest arteries around the trophoblast early in the first trimester of normal pregnancies to try to elucidate the timing and magnitude of the changes that cause the decrease in peripheral vascular resistance.

S/D, Peak systolic to end-diastolic ratio.

Material and methods

Fifty healthy women were included in the study. All had at least one previous normal delivery. Their menstrual cycles were regular and all had accurately dated gestations by ultrasonography and dates. Included were only pregnancies in which heart activity could be detected and only those that progressed normally into the second trimester. The scans were performed with an Aloka SSD 680 scanner (Aloka Ltd., Japan), with the use of a 5 mHZ vaginal transducer with color and pulsed-wave Doppler. Ten women of each gestational age, 5 to 9 weeks, were studied only once. Flow around the trophoblast was identified by the appearance of color and two to four Doppler measurements from different sites were performed at each examination. The peak systolic to end-diastolic ratio (S/D) and resistance index were calculated with the formula:

$$RI = (S - D)/S$$

where RI is resistance index, S is peak systolic and D is end-diastolic measurement. The difference between any two measurements on each examination did not exceed 8% and the mean was considered a good estimation of the actual ratios. On each measurement three waves were calculated and the mean S/D ratio and resistance index were noted. The final result was obtained by calculation of the mean S/D ratio and resistance index for all measurements at their respective gestational age.

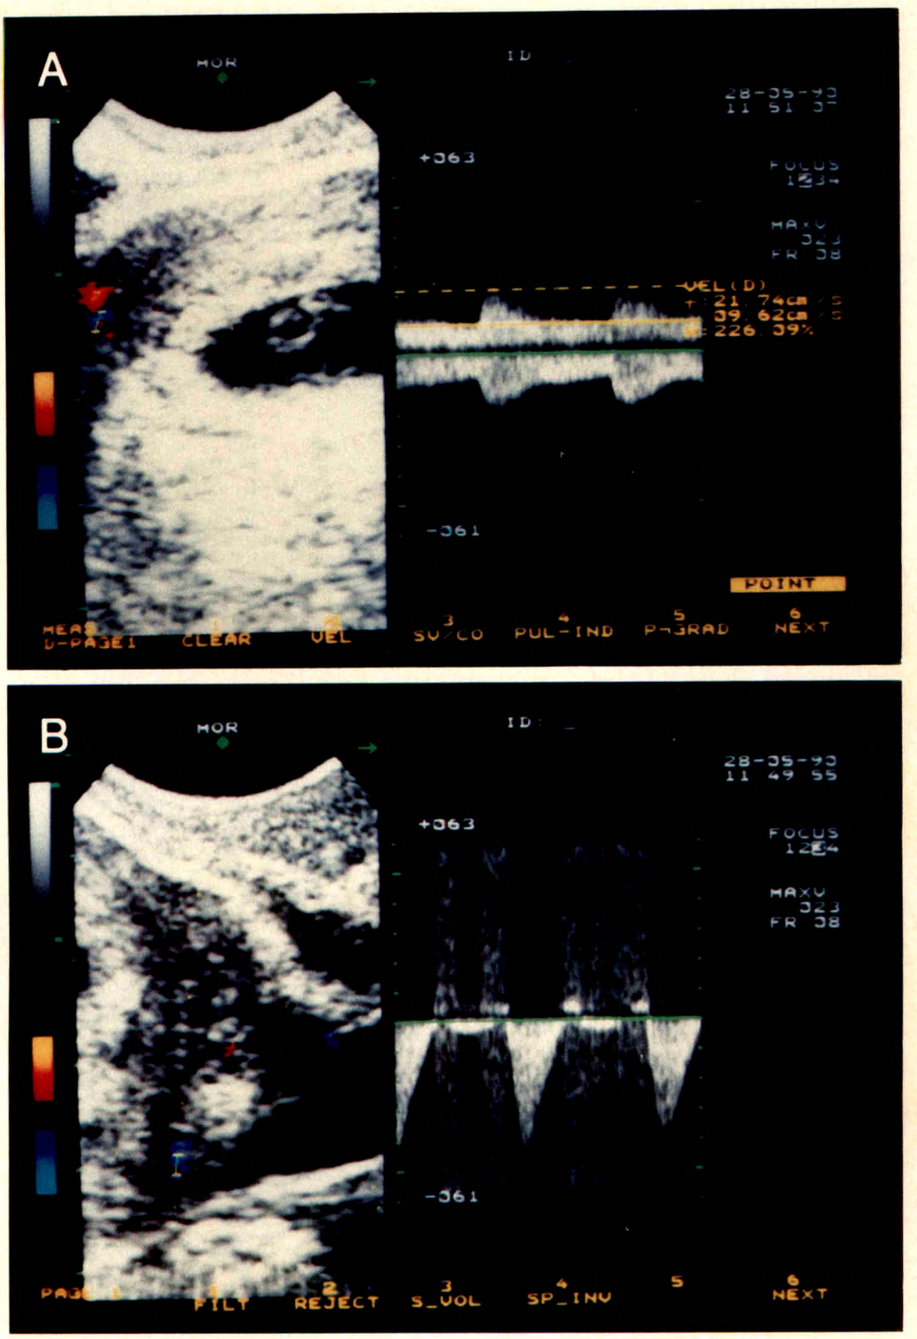

Fig. 3. Color Doppler imaging of trophoblastic flow **(A)** in 7-week pregnancy as compared with flow in uterine artery **(B)**.

Results

The changes in S/D ratios and resistance index with gestational age are depicted in Table I. The blood flow around the trophoblast could not be detected in four women at 5 weeks' gestation and in two women at 6 weeks' gestation. The flow was detected in all women from week 7 onward. Figs. 1 and 2 are examples of the blood flow detected by color imaging. Both figures show the high diastolic flow characteristic of a low-impedance organ. The results in Table I, with lower-than-anticipated S/D ratios and resistance index, show that the blood flow near the trophoblast has a prominent diastolic component as early as 5 weeks' gestation.

Comment

Doppler waveforms of the uterine artery in the normal nonpregnant uterus were previously described.[17] It was also shown by several authors that at some time in the second trimester the blood flow in the uterine arteries changes with the appearance of a high-diastolic component.[5, 6, 7, 15] One of the explanations behind this phenomenon is that at some time in the early pregnancy there is a trophoblastic invasion of the myometrial segments of the spiral arteries, causing the conversion of the uterus into a low-resistance organ with a high-diastolic blood flow.[20] Doppler technology provides the tool to follow the patterns and changes in the uterine circulation during pregnancy and any deviation from the normal can be observed. Both the continuous-wave Doppler system and the pulsed-wave system were used in previous studies of the uterine arteries.[1, 8, 15, 18] With both systems the ultrasonographic beam is directed toward the anatomic location of the uterine artery until the typical waveform pattern is obtained.[1, 15, 18]

Several studies reported the progressive decline in peripheral vascular resistance of the uterine vessels during pregnancy as shown by Doppler waveforms. These studies generally measured Doppler waveforms starting in the second trimester and reported the results obtained from the uterine arteries or their main branches. With the continuous-wave Doppler technique the signal can be from the sum of more than one artery,[18] and because it is a blind technique it is unlikely to measure the same location on consecutive examinations.[10, 15, 19] Differences of measurements as a result of placental location cannot be properly assessed by this method. With the pulsed-wave technique the blood flow must be measured from a vessel large enough to be seen by real-time ultrasonography to make it reproducible.

With the development of the color Doppler imaging this concept has changed. We can now identify blood flow wherever color is displayed by the Doppler signals and thus measure blood flow in vessels too small to be visualized.[20] Results of previous Doppler studies of the uterine arteries showed a high S/D ratio in early pregnancy[15] and a decrease toward the middle of the second trimester. This study for the first time of which we are aware shows a discrepancy between uterine blood flow measurements noted in previous studies and subtrophoblastic blood flow. We showed that the characteristic changes of the waveform occur at a much earlier stage of gestation at the level of the smallest arteries surrounding the trophoblast, as compared with the main uterine artery branches where similar changes do not occur until the second trimester. Fig. 3 shows an example of the Doppler measurement of the trophoblastic flow and the uterine artery flow illustrating this difference.

With the introduction of transvaginal color Doppler imaging it is hoped that it will be possible to detect diseases of placental structure and function in the first trimester. The role of this technique for determination of fetal viability and fetal or maternal disorders needs to be explored.

Small-for-gestational-age birth: Maternal predictors and comparison with risk factors of spontaneous preterm delivery in the same cohort

Barbara Abrams, DrPH, RD, and Vicky Newman, MS, RD
Berkeley, San Francisco, and San Diego, California

Low birth weight, the primary predictor of infant mortality and morbidity, can be a result of shortened gestation (preterm delivery) or fetal growth retardation (small for gestational age). We examined the relationship between maternal characteristics and the risk of delivering a small-for-gestational age infant in 2228 women who participated in the University of California, San Diego Prenatal Nutrition Project between 1978 and 1988. A multivariate analysis indicated that significant risk factors for small for gestational age were cigarette smoking (odds ratio, 3.18), a low rate of maternal weight gain (odds ratio, 2.96), black ethnicity (odds ratio, 2.60), pregravid underweight (odds ratio, 2.36), Asian ethnicity (odds ratio, 1.88), primiparity (odds ratio, 1.85), and low maternal height (odds ratio, 1.63). These findings are contrasted with those previously published on preterm deliveries in the same cohort. We conclude that with the exception of black ethnicity and low maternal weight gain, different maternal characteristics were significantly associated with small-for-gestational-age and preterm birth in this population. (Am J Obstet Gynecol 1991;164:785-90.)

Key words: Risk factors, small for gestational age, low birth weight, weight gain

Low birth weight, the primary predictor of infant mortality and morbidity,[1-3] can be a result of shortened gestation (preterm delivery) or fetal growth retardation (small for gestational age, SGA). Because different factors may be associated with preterm delivery and SGA,[4] an understanding of the specific determinants of each is essential to design interventions to reduce their occurrence.

We described the relationship between maternal characteristics and spontaneous preterm delivery in a cohort of more than 2000 women who participated in the Prenatal Nutrition Project at the University of California, San Diego over an 8-year period.[5] Multivariate analysis of the data suggested that incompetent cervix (odds ratio, 6.15), use of illicit drugs during pregnancy (odds ratio, 3.90), exposure to trauma, surgery, or anesthesia during pregnancy (odds ratio, 3.47), maternal age <16 years (odds ratio, 2.91), black ethnicity (odds ratio, 2.10), low rate of maternal weight gain (odds ratio, 1.59) and short interpregnancy interval (odds ratio, 1.77) were significant risk factors of spontaneous preterm birth.

The objective of this article is to describe how ma-

ternal characteristics related to the risk of SGA birth and to contrast these findings with those of our earlier study of preterm births in the same population.

Material and methods

The University of California, San Diego Prenatal Nutrition Project provided nutritional assessment and counseling to pregnant women considered at high risk of the development of nutritional problems during pregnancy. Information on demographics, diet, behavioral factors (such as cigarette smoking and use of illicit drugs), and medical and obstetric history were obtained by interview. Data on pregnancy course and outcome were obtained by chart review shortly after delivery. These data were entered into a computerized data base. Additional information on the cohort and on data collection procedures were previously published.[5]

For this analysis, the study group included all Prenatal Nutrition Project participants who were delivered of infants between January 1978 and December 1988 and whose pregnancies were uncomplicated by antepartum death, twin gestation, or major congenital anomalies.

Maternal characteristics selected for study were determined on the basis of previous reports of factors associated with SGA.[2, 3, 6-8] Prepregnancy weight was based on maternal recall at the first visit. Several studies suggest that self-reported weight reflects measured weight in women.[9-11] The single report on the accuracy of recalled pregravid weight, conducted in adolescents, concluded that although there was some variability in individual women, for the group as a whole, recalled prepregnancy weights correlated very closely with measured pregravid weight.[12] Maternal pregravid weight for height was based on the 1959 Metropolitan Insurance standards of desirable weight for height,[13] and divided into the following categories: underweight (<90%), ideal weight (90% to 119%), overweight (120% to 135%), and obese (>135%).

Total pregnancy weight gain was estimated by subtracting the prepregnancy weight from the last measured weight before delivery. Maternal weight gain was treated as a weekly rate of gain, estimated by dividing total weight gain by the gestational age at which the last weight measurement was made, minus 2 weeks subtracted from the denominator because gestational age was based on the last menstrual period. Low rate of gain was defined as <0.27 kg/week, which represents a total maternal weight gain of <10 kg at 40 weeks' gestation.

Each infant was classified as SGA (less than the 10th percentile), average for gestational age (AGA) (10th to 90th percentile), or large for gestational age (LGA) (greater than the 90th percentile) with the use of reference standards for birth weight for gestational age and sex published for California.[14] Gestational age was estimated primarily on the basis of maternal recall of the last menstrual period (LMP) and to a lesser extent on ultrasonographic or Dubowitz examinations. To ensure that infants were properly classified as preterm or term, the medical records of all infants with a birth weight <2750 gm or gestational age <38 weeks were reviewed by an obstetrician who specialized in maternal-fetal medicine.[5] However, no review was conducted for pregnancies that lasted >38 weeks' gestation or for infants who weighed >2750 gm. Because there is evidence that pregnancies are often erroneously classified as post dates on the basis of maternal LMP,[15, 16] infants with gestational ages >40 weeks were classified as SGA on the basis of the birth weight cutoff for 40 weeks (2944 gm for male infants and 2817 gm for female infants). Thus we used a conservative definition of SGA, and 19 infants who would be classified as post date SGA with the use of a gestational age of >40 weeks were classified as AGA. After classifying the infants according to birth size for gestational age, all LGA infants were eliminated from the analysis because LGA is associated with increased morbidity and mortality and has been shown to have different (and somewhat opposite) risk factors than those of SGA.[17, 18]

Differences in the distribution of maternal characteristics with the SGA and AGA groups were examined by cross tabulation with the use of χ^2 analysis. We then used a series of multiple logistic regression models to estimate the significance of each factor and its magnitude of risk in the prediction of SGA in this study group while controlling for the influence of the other factors. The analysis began with all factors in Table I included. Variables were then removed, one at a time, on the basis of both knowledge about the relationships between the factors and statistical significance, until only those variables remained that were significant predictors of SGA. Odds ratios, adjusted for the other significant predictors of SGA, and their 95% confidence intervals were calculated from the logistic coefficients and SEs estimated in the final model. Each odds ratio approximates the risk of SGA for women who were exposed to each risk factor, compared with the risk of SGA for women who were not exposed and adjusting for the other factors significantly associated with SGA birth in this study group. An odds ratio is statistically significant if its confidence interval excludes 1.0. Results for all analyses were considered significant if the two-tailed p value was <0.05.

Results

The ethnic distribution of mothers in the study group was 41% white, 32% Hispanic, 15% black, 11% Asian (primarily of Southeast Asian origin) and <1% other ethnicity. A total of 51% of the mothers were pri-

*Overall incidence of SGA birth in the sample was 9.8%.
†Includes both preexisting and pregnancy-induced.

miparous and 71% were low income. Mean maternal age was 24.0 years (SD, 5.5). Of the 2228 women in the study group, 219 were delivered of SGA infants and 2009 were delivered of AGA infants. Thus the incidence of SGA was 9.8%. Mean birth weight was 2510 gm (SD, 324.5) in the SGA group and 3350 gm (SD, 335.1) in the AGA group ($p < 0.0001$).

Table I shows that the SGA group had a higher frequency of women who were primiparous, black or Asian, low income, and unmarried. A higher percent of SGA mothers reported that they smoked cigarettes (>10 per day) and used illicit drugs. Compared with AGA mothers, SGA mothers were more likely to have short stature, begin pregnancy underweight for height, and have a low weekly rate of weight gain during pregnancy. There was significantly more hypertension (essential or pregnancy-induced) among SGA mothers. Alternatively, Hispanic ethnicity, prenatal care during the first trimester, maternal overweight, and diabetes were factors that occurred significantly less frequently among SGA mothers. Other risk factors including extremes of maternal age, unplanned pregnancy, short interpregnancy interval, maternal energy intake, and maternal obesity were not significantly related to SGA by univariate analysis.

Significant predictors of SGA from the multiple logistic model are shown in Table II. Two maternal characteristics were each associated with a tripled risk of SGA: smoking more than 10 cigarettes per day (odds ratio, 3.18) and a low weekly maternal weight gain during pregnancy (odds ratio, 2.96). The risk of SGA was more than doubled in women who were black (odds

Table II. Significant predictors of SGA by logistic regression analysis

Parameter	*Adjusted odds ratio*	*95% Confidence interval*
Cigarette smoking (>10/day)	3.18	2.06, 4.91
Low rate of maternal weight gain	2.96	2.17, 4.04
Black ethnicity	2.60	1.82, 3.71

Primiparity	1.85	1.35, 2.64
Low maternal height	1.63	1.03, 2.44

ratio, 2.60), who began pregnancy with a low maternal weight for height (odds ratio, 2.36), or who had hypertension during pregnancy (odds ratio, 2.07). Other factors significantly related to SGA in the model were Asian ethnicity (odds ratio, 1.88), primiparity (odds ratio, 1.85) and low maternal height (odds ratio, 1.63).

Comment

Before discussing the results, several limitations in study design and execution should be noted. First, because it is a convenience sample, the Prenatal Nutrition Project Cohort cannot be directly generalized to other populations. Second, measurement of some of the variables including illicit drug use was not the original focus of the study. For example, rather than screening all women for illicit drug abuse in a standard fashion, drug abuse was diagnosed either when the pregnant woman admitted using drugs during the prenatal interview or when there was obvious behavioral or physical evidence of drug abuse during the course of pregnancy or at delivery. For this reason, we are less confident of results relating to these variables than others, such as maternal body size or ethnicity. Third, correct classification of infants as SGA is made on the basis of accurate estimation of gestational age, which is difficult in any study that is based on clinical data. We attempted to remedy this problem by reexamining the gestational ages of all small infants or those with gestational ages <38 weeks, and we used a conservative estimate of SGA for all infants who were delivered after 40 weeks' gestation.

The fourth potential limitation also relates to our ability to properly classify infants as SGA. The definition we used was based on a standard that identified sex-adjusted, gestational-age-specific cutoffs (below the 10th percentile) for fetal birth weight that were associated with the lowest perinatal mortality in California. Sex-adjusted standards were selected because although females have lower average birth weights than those of males, the difference is not associated with differences in the distribution of risk factors or in outcome.[4]

The question of whether to adjust for other maternal factors that are associated with birth weight, such as race, parity, or body size, is controversial.[19] For example, evidence that at the same low birth weight, black infants have a lower mortality rate than that of white infants, suggests that the fetal growth curve and its relationship to mortality may differ between white and black infants.[20] The fact that black infants are larger than white infants at early gestational ages and smaller at later ones[20, 21] suggests a biologic basis for differences in growth, and this has led to the suggestion that lower cutoffs for low birth weight and SGA be used for black women. However, there are also data that suggest that fetal growth is influenced more by maternal behavior than by genetics. For example, a study contrasted maternal health behaviors and birth weight in a population of black prenatal patients who were foreign-born and U.S.-born. The foreign-born mothers reported fewer behavioral risk factors for low birth weight; even after controlling for a variety of social, physical, and behavioral risk factors, their infants were on average 135 gm heavier than those of mothers born in the United States.[22] Thus the influence of race on birth weight is complex and still poorly understood. The use of race-adjusted standards can obscure the fact that blacks have disproportionately more low birth weight infants than do whites. In addition, standards that simultaneously adjust for race and sex or other maternal characteristics have not been published for California, thus the standards used in this study were simply sex-adjusted.

However, because the only sex-adjusted California standards were determined on the basis of the white, non-Spanish percentiles, if black (and possibly Southeast Asian) infants truly do better at lower birth weights than white infants, our analysis will have classified some infants in those racial groups as SGA when in fact they might be of appropriate size. If this is the case, the relationships we found between maternal risk factors and SGA are conservative, suggesting that if lower birth weight cutoffs were used, the associations would be even stronger.

In addition, because the standards used were based on population-based statistical data rather than clinical measurements, the definition of SGA cannot discriminate between infants of any race who were growth retarded or simply small, but well-grown.

Finally, because our study was observational in nature, we are unable to definitively say whether any risk factor was simply associated with or caused SGA birth.

Whereas these are important limitations, all the maternal characteristics that significantly predicted SGA in this cohort were previously linked with an increased

risk of SGA in other populations.[2, 3, 6-8] For this reason, we believe that the results reported here are relevant to other populations.

The first objective of this study was to evaluate the relationship between maternal characteristics and the risk of SGA in this cohort. First we examined the relationship between SGA and each factor one at a time. Then we entered all the factors simultaneously into the multivariate model to determine which of the maternal characteristics were independently related to SGA after controlling for the influence of the others. Cigarette smoking, black and Asian ethnicity, maternal hypertension, primiparity, low maternal height, pregravid weight, and weight gain each significantly predicted SGA in the multivariate model. These findings are similar to those recently reported in a Finnish case-control study of severely SGA neonates (defined as birth weight below the 2.5th percentile).[23] In that study of presumably white women only, the most important risk factors associated with SGA delivery were low maternal prepregnancy weight, history of previously being delivered of an SGA infant, low pregnancy weight gain, toxemia, and cigarette smoking.

The second objective of this study was to contrast the risk factors of SGA with those for preterm delivery. The analysis of preterm delivery for this population were reported in detail elsewhere.[5] Table III shows that although 13 different risk factors were significantly associated with either SGA or spontaneous preterm birth, only black ethnicity and a low weekly rate of maternal weight gain were associated with both.

We could identify only a few other studies that examined the relationship between maternal factors and both impaired fetal growth and preterm delivery in the same cohort. Villar et al.[7] studied a small group of women in rural Guatemala and reported that after multivariate analysis only a low maternal head circumference was significantly associated with intrauterine growth retardation, whereas maternal energy supplementation, protein supplementation, and low arm circumference were associated with preterm delivery.

Another study[24] examined how a variety of maternal risk factors predicted SGA and preterm delivery in a Canadian cohort. SGA was defined as birth weight below the 10th percentile but not preterm, whereas preterm was defined as birth before 37 weeks' gestation but not SGA. Although a variety of different maternal characteristics were associated with each outcome in the univariate analyses, after multivariate analysis, the only significant predictors of SGA were maternal height and prepregnancy weight, and the only significant predictors of preterm birth were maternal education and household income level.

Another study[25] contrasted 12 maternal risk factors of SGA and preterm delivery among 17,000 low-income women in Birmingham, Alabama, between 1983 and 1987. After multivariate analysis, SGA was significantly associated with black race, primiparity, increased maternal age, maternal smoking, low maternal height and weight, and a low rate of maternal weight gain during the last 20 weeks' gestation. Preterm delivery was significantly associated with black race, unmarried status, low and high maternal age, maternal smoking, low maternal weight, and both a low and high rate of maternal weight gain during the last 20 weeks' gestation. The authors suggested that the high rate of maternal weight gain associated with preterm delivery may have been a result of medical intervention in response to pregnancy-induced hypertension and its associated high weight gain, but they could not explain why maternal drug use was associated with a significantly decreased risk of preterm delivery.

In a study conducted in Brazil,[26] the authors found that both preterm delivery and intrauterine growth retardation were associated with low maternal weight, smoking, and few antenatal visits, whereas young maternal age was related to preterm birth and a low maternal education was related to growth retardation. Gestational weight gain was not reported. On the basis of these results, the authors concluded that low birth weight would be reduced with improvements in maternal nutrition, cessation of smoking, reduction in births to young women, and improved prenatal care.

These published reports support our finding that different maternal characteristics are associated with

SGA versus preterm birth. The fact that the specific risk factors associated with either SGA or preterm delivery and their magnitude vary among the studies may be because of differences in methods (e.g., the way SGA or preterm births were defined, sample size, definition of the independent variables) or it may reflect real differences in risk among different populations.

In a critical meta-analysis of the published literature on determinants of low birth weight, Kramer[2, 4] concluded that in developed countries the most important maternal risk factors of intrauterine growth retardation included cigarette smoking, low maternal caloric intake or weight gain, low pregravid weight, primiparity, short stature, nonwhite race, and maternal history of low birth weight or previous delivery of a low-birth-weight infant. On the other hand, cigarette smoking, prior history of preterm birth or spontaneous abortion, low prepregnancy weight, and in utero exposure to diethylstilbestrol were the most important established maternal risk factors of preterm birth.

Low birth weight continues to be a significant public health problem. In this cohort, eight different common maternal risk factors of SGA were identified, confirming the results of other studies. In addition, our data suggest that different maternal factors are associated with SGA as compared with preterm delivery. Although only a few of the factors identified offer an opportunity for intervention, improvement of knowledge about the specific maternal characteristics that relate to SGA or preterm delivery may allow better identification or care of women who are at risk.

We thank Donald Rose for assistance with data processing, and Dale Ogar for editorial assistance.

Antisperm antibodies to sperm surface antigens in women with genital tract infection

Dean S. Cunningham, MD, PhD,[a] David L. Fulgham, BS,[b] David L. Rayl, MD,[a] Keith A. Hansen, MD[a] and Nancy J. Alexander, PhD[b]

Portsmouth and Norfolk, Virginia

Antisperm antibodies to sperm surface antigens in nulligravid women with primary upper genital tract infections were measured by the sperm mixed agglutination reaction assay. As many as 56% of women with a primary episode of pelvic inflammatory disease had antisperm antibodies. In addition, 69% of those women with no history of genital tract infection but with laparoscopic evidence of past pelvic infection had significant levels of circulating antisperm antibodies. Electroimmunoblots of sperm preparations probed with the sera of women who had either known or presumed upper genital tract infection revealed a uniformly recognized 69 kd antigen. In contrast, women with circulating antisperm antibodies before primary upper genital tract infection recognized up to five distinct sperm antigen determinants of 27, 54, 131, 146, and 174 kd. It is a distinct possibility that genital tract infections may lead to immunopotentiation of antisperm antibodies that could affect fertility. (AM J OBSTET GYNECOL 1991;164:791-6.)

Key words: Antisperm antibodies, genital tract infection, Western blot analysis, sperm surface antigens, infertility

Occasionally, both men and women have measureable antibodies that are directed against spermatozoan antigens. More commonly, couples with idiopathic infertility have antisperm antibodies.[1] Although the mechanism underlying antisperm antibody production is unknown, it has been proposed that it arises, among other ways, as a consequence of local inflammation.[2] Thus genital tract infections might serve as nonspecific immunopotentiators that lead to the production of antisperm antibodies. Therefore in this study we evaluated the relationship between genital tract infection and antisperm antibody production.

Material and methods

Patients. The study patients were nulligravid women 18 to 30 years old with no history of autoimmune disorders, gynecologic infections, or abdominopelvic surgery. They were seronegative for the human immunodeficiency virus. The patients were placed by diagnosis into one of five groups: (1) stage I pelvic inflammatory disease,[3,4] (2) stage II pelvic inflammatory disease,[3,4] (3) trichomonas vaginitis, (4) candida vaginitis, or (5) chlamydial cervicitis. The diagnoses of trichomonas and candida vaginitis were based on symptoms, character of vaginal discharge, vaginal pH, and the presence of trichomonads on saline solution preparation or hyphae and/or spores on potassium hydroxide preparation, respectively. Patients were considered to have chlamydial cervicitis when a cervical swab specimen was reactive in an enzyme-linked immunosorbent assay for *Chlamydia trachomatis* antigen, when >10 white blood cells per high-power field on a saline solution preparation of vaginal discharge was observed, and when pelvic examination results were insufficient to satisfy criteria for the diagnosis of pelvic inflammatory disease. Sexually active women who were free of genital tract infection and who met the previously described exclusion criteria were recruited as a control group during routine annual gynecologic examination. Two additional groups of patients consisted of patients with primary infertility who were undergoing diagnostic laparoscopy and were found to have either pelvic adhesive disease or hydrosalpinx without pelvic adhesive disease. Both written and verbal informed consent were obtained from all participants in an institution-approved protocol.

Five milliliters of venous blood was collected from each patient when she was admitted to the study and

Control (n = 50)	4 (8%)	2 (4%)

again at the 4-week follow-up visit. Individual blood samples remained at room temperature for 1 hour for clot formation and for 2 hours at 4° C for clot retraction. The samples were centrifuged at 1200 *g* for 15 minutes. The resultant sera were inactivated at 56° C for 30 minutes and were stored at −80° C until they were used. One hundred microliters of cervical mucus was aspirated from each patient both at study entry and at follow-up evaluation. The cervical mucus was applied to a gel filtration column, and the eluate containing molecular weight fractions that correspond to immunoglobulins A and G was separately recovered, dialyzed overnight against a large volume of Dulbecco phosphate-buffered saline solution (DPBS) at 4° C, lyophilized, and reconstituted to the original volume in DPBS before it was stored at −80° C. No attempt was made to collect the follow-up samples of sera or cervical mucus at any specific time of the menstrual cycle, because the initial samples were obtained at different times of diagnosis.

Sperm mixed agglutination reaction test. The indirect sperm mixed agglutination reaction test was used to screen patient sera or cervical mucus for the presence of antisperm antibodies of the immunoglobulin G class, as described by Ackerman et al.[5] The serum or cervical mucus sample was considered positive when at least 40% of the motile sperm was bound to beads.

Sperm antigen extracts. Four semen samples were obtained from healthy donors who were shown to be negative for antisperm antibodies by the direct sperm mixed agglutination test.[5] Spermatozoa were collected by the swim-up technique[6] and resuspended at 60 × 10^6/ml in DPBS before being suspended in 50 mmol/L of Tris hydrochloride (pH 7.4) containing 10 mmol/L CHAPS (3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate; Pierce Chemical Co, Rockford, Ill.). The sperm suspension was then placed in a Pyrex tube on ice and repeatedly sonicated in 10-second pulses at a setting of 20 kHz on a Biosonic III sonicator (Bronwill Scientific, Rochester, NY). Protease inhibitors (aprotinin 100 U/ml, 2 mmol/L pepstatin A, and 2 mmol/L phenylmethylsulfonyl fluoride; all from Sigma Chemical Co., St. Louis) were added to the extract, and the resulting suspension was rotated overnight at 4° C to allow for maximum solubilization. The sperm antigen preparation was then centrifuged at 85,000 *g* for 1 hour at 4° C, and the supernatant fluid containing solubilized sperm antigens was dialyzed overnight against a large volume of DPBS at 4° C. The protein concentration was determined by Bradford[7] analysis, and aliquots of the sperm extracts were stored at −80° C until they were used.

Electrophoresis and protein blotting. Sperm antigen extracts were analyzed by electrophoresis in polyacrylamide slab gels containing 0.1% sodium dodecyl sulfate with a 5% (wt/vol) polyacrylamide stacking gel and a 12.5% (wt/vol) polyacrylamide resolving gel in buffered Tris glycine, as described by Laemmli.[8] Samples containing sperm components were reduced and denatured by boiling in an equal volume of sample buffer (0.08 mol/L Tris hydrochloride [pH 6.8], 0.1 mol/L DL-dithiothreitol, 2.0% sodium dodecyl sulfate, and 10% glycerol) for 2 minutes before application to the gels.

The following standard proteins were used as molecular weight markers: myosin (200 kd), β-galactosidase (116.25 kd), phosphorylase b (92.5 kd), bovine serum albumin (66.2 kd), ovalbumin (45 kd), carbonic anhydrase (31 kd), soybean trypsin inhibitor (21.5 kd), and lysozyme (14.4 kd) (all from Bio-Rad Laboratories, Richmond, Va.).

Sperm antigen extracts resolved by sodium dodecyl sulfate–polyacrylamide gel electrophoresis were transferred to nitrocellulose membrane strips. Nitrocellulose membranes (0.45 μm pore size; Bio-Rad Laboratories), sponges, and filter papers were preequilibrated in cold transfer buffer (25 mmol/L Tris hydrochloride [pH 8.3], 192 mmol/L glycine, and 20% [vol/vol] methanol) for 2 hours before use. Proteins were electrophoretically transferred from the gel onto 8-mm-wide strips of nitrocellulose at 30 V for 12 to 14 hours at 4° C. The efficiency of transfer was determined by staining selected strips that contained antigen and strips containing molecular weight markers in 0.1% (wt/vol)

amido black in 40% (vol/vol) methanol–2% (vol/vol) acetic acid. Strips were destained in 70% (vol/vol) methanol–7% (vol/vol) acetic acid. Under these conditions protein transfers were reproducible over a wide range of molecular weights.

Sperm antigen detection. Nitrocellulose strips containing sperm proteins resolved by sodium dodecyl sulfate–polyacrylamide gel electrophoresis were analyzed by an indirect enzyme-labeled antibody assay. The strips were rinsed in DPBS after the electrophoretic transfer and incubated in DPBS containing 3% normal goat serum and 0.1% Tween 20 (all from Sigma Chemical Co.) for 2 hours as a blocking step. All incubations in the assay were performed in 25-well acrylic incubation trays (Bio-Rad Laboratories) that were placed in a high-humidity shaking water bath set at 37° C. The primary antisera used in the assay were the various patient sera samples (diluted 1:50 in DPBS containing 10% fetal bovine serum). Horseradish peroxidase–conjugated goat antihuman immunoglobulin A or G (Fisher Scientific Co., Springfield, N.J.), which was diluted 1:1000 in DPBS, was used as a second antibody. Strips were incubated in 10 ml of each of the antiserum preparations for a period of 1 hour with three 10-minute washes in DPBS containing 0.1% Tween 20 after each incubation. The strips were then developed in 120 ml of substrate solution (0.34 mmol/L 4-chloro-1-napthol dissolved in 20 ml of cold methanol and diluted in 100 mmol/L Tris–saline solution buffer that consisted of 0.04 mol/L Trizma hydrochloride, 9.7 mmol/L Trizma base, and 0.2 mol/L sodium chloride, pH 7.4; all from Sigma Chemical Co.) that was activated by the addition of 60 μl of 30% hydrogen peroxide.

Molecular weight determinations of the immunoprobed sperm antigens were made by polynomial regression analysis.

Results

The sperm mixed agglutination reaction test was used to screen women with primary genital tract infection for antisperm antibodies. The results of this test are presented in Table I. As many as 46% of women with stage I pelvic inflammatory disease had serum and cervical mucus antisperm antibodies of the immunoglobulin G class within 4 weeks of initial presentation and diagnosis. Similar findings were observed with women who had stage II pelvic inflammatory disease. A significant percentage of women with lower genital tract infections also had antisperm antibodies; however, antibody activity was demonstrated in <20% of all these patients tested. Women with no history of gynecologic infections but with laparoscopy verified pelvic adhesive disease or hydrosalpinx without adhesions had antisperm antibodies nearly 70% of the time. In our population the background antisperm antibody activity was

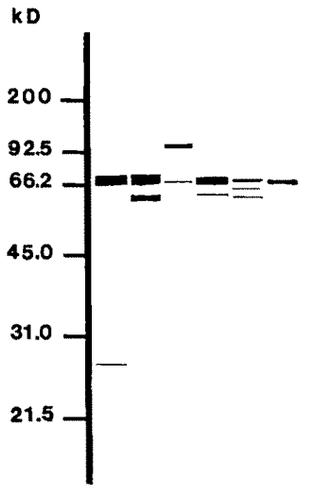

Fig. 1. Detection of sperm antigens by immunoblot analysis. *Lanes 1 to 3*, Sperm antigen detection by probe with sera from representative patients with stage I pelvic inflammatory disease. *Lanes 4-6*, Sperm antigen detection by probe with sera from representative patients with stage II pelvic inflammatory disease.

generally <10%, and no antisperm antibodies were demonstrated in the sera obtained from 17 women tested who had no history of exposure to spermatozoan antigens (data not shown). With the exception of the group of patients with distal tubal disease, the women studied had no differences in antisperm immunoglobulin G activity between the serum and cervical mucus. In this group approximately one third of patients with serum antisperm antibodies did not have measurable activity in the cervical mucus aspirate.

Fig. 1 is a display of immunoblots that are representative of patients with stage I (lanes 1 to 3) or stage II (lanes 4 to 6) pelvic inflammatory disease. A dominant 69 kd band was identified in all sera tested from these patients; no other constituent bands appeared uniformly. These results were found to be similar whether pooled semen or semen from the patient's current sexual partner only was used as a source of sperm antigens (data not shown). The sperm protein bands identified after the preparative gel was stained were similar, regardless of antigen preparation technique (freeze-thaw sonicate, biotinylated purification, NP-40 extraction, CHAPS extraction; data not shown).

As shown in Fig. 2, when sera from patients with antisperm antibody activity at the time of upper genital tract infection diagnosis were compared with paired sera at follow-up evaluation, there were numerous detectable bands, none of which included the 69 kd band identified in patients without preexisting antisperm antibody activity. The collective antigen bands from all patients migrated with molecular weight markers of 27,

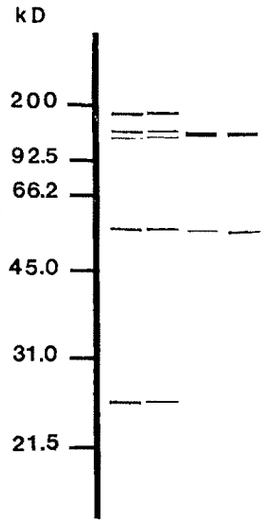

Fig. 2. Detection of sperm antigens by immunoblot analysis. *Lanes 1 and 2,* Acute and convalescent sera from representative patient with stage I PID and preexisting antisperm antibodies. *Lanes 3 and 4,* Acute and convalescent sera from representative patient with stage II pelvic inflammatory disease and preexisting antisperm antibodies.

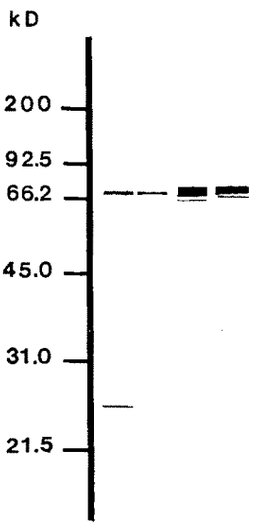

Fig. 3. Detection of sperm antigens by immunoblot analysis. *Lanes 1 and 2,* Sera from representative patients with pelvic adhesive disease. *Lanes 3 and 4,* Sera from representative patients with distal tubal disease.

54, 131, 146, and 174 kd. All five protein bands were detected in some (but not all) sera samples. In no case was the antigen band profile different in the serum obtained at diagnosis when compared with the serum obtained at follow-up evaluation.

Patients with presumptive evidence of a past upper genital tract infection at diagnostic laparoscopy had antigen band patterns that resembled those of patients with a primary upper genital tract infection (compare Fig. 3 with Fig. 1). The 69 kd antigen was consistently recognized; other antigens were not recognized consistently.

Fig. 4 is a collection of immunoblots from patients without a history of upper genital tract infection. Lane I shows the antigen band pattern of a woman with antisperm antibodies and no history of either upper or lower genital tract infection. When all patients were considered together, the antigen bands were restricted to the molecular weight ranges found in patients with preexisting antisperm antibody activity (Fig. 2). Lanes 2 and 3, 5 and 6, and 8 and 9 represent the antigen bands detected in the presentation and follow-up sera of patients with trichomonas vaginitis, candida vaginitis, and chlamydia cervicitis, respectively. These paired samples show antigens that are characteristic of women with preexisting antisperm antibody activity and no new antigen bands. Lanes 4, 7, and 10 represent the follow-up sera samples from patients with no preexisting antisperm antibody activity who were diagnosed with primary trichomonas vaginitis, candida vaginitis, and chlamydial cervicitis, respectively. Once again, no antigenic determinants stained other than the 27, 54, 131, 146, and 174 kd bands demonstrated in patients with preexisting antisperm antibodies (compare Fig. 4 with Fig. 2).

The lanes in Fig. 5 are comparisons of immunoglobulin isotypes in cervical mucus from patients without a history of genital tract infection (lanes 1 and 2), stage I pelvic inflammatory disease (lanes 3 and 4), and stage II pelvic inflammatory disease (lanes 5 and 6). All cervical mucus samples had been screened with the sperm mixed agglutination reaction test and were known to have antisperm antibodies of the immunoglobulin G class only before immunoprobe analysis for immunoglobulin A. The probed antigenic bands detected by antisera against immunoglobulins G and A differed in all samples tested and included many antigenic band molecular weights that were not detected in the sera samples (28, 58, 87, 96, 140, 201, 244, and 311 kd). No antigenic band was consistently detected, as was the case with the 69 kd band in women with upper genital tract infection or the five antigenic bands in women with preexisting antisperm antibodies or lower genital tract infections.

Comment

In this study we have demonstrated a relationship between genital tract infection and the production of antisperm antibodies in some (but not all) nulligravid

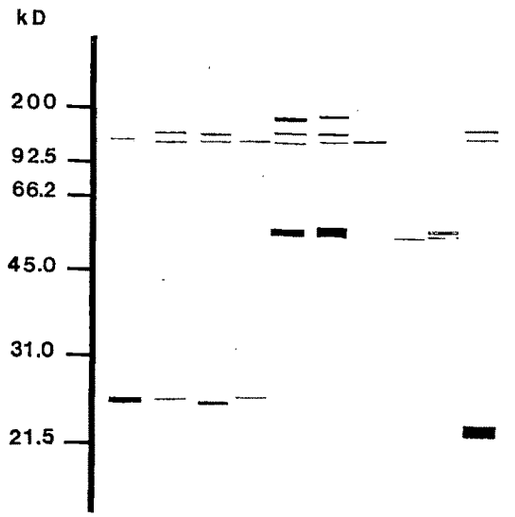

Fig. 4. Detection of sperm antigens by immunoblot analysis. *Lane 1,* Sera from representative patient with antisperm antibody activity and no history of genital tract infection. *Lanes 2 and 3, 5 and 6, and 8 and 9,* Acute and convalescent sera from representative patients with trichomonas vaginitis, candida vaginitis, and chlamydia cervicitis, respectively, as well as preexisting antisperm antibodies. *Lanes 4, 7, and 10,* Convalescence sera from representative patients with trichomonas vaginitis, candida vaginitis, and chlamydia cervicitis, respectively, with no preexisting antisperm antibodies.

women. This is not without precedent; Witkin and Toth[2] have shown that antisperm antibodies developed in a similar percentage of men with urethritis, and Blum et al.[9] described a very significant correlation between antisperm antibodies and antichlamydial antibodies in oral contraceptive users. We confirmed these general findings and also showed a striking difference in the characteristics of humoral responses generated against spermatozoa.

We have shown that in nearly 50% of women with a primary upper genital tract infection, antisperm antibodies develop against a restricted set of antigens. The immunodominant antigen is universally recognized as having a molecular weight of 69 kd. This pattern is distinct from that in women with lower genital tract infections who had a limited but overlapping repertoire of detected antigens. When they have been established, antisperm antibody specificities are apparently immutable, as evidenced by the group of women with preexisting antibody activity that antedated the primary genital tract infection. These findings suggest an underlying immunoregulatory event, and indeed Witkin[10, 11] has produced ample data to support a break in immunoregulation as the basis for antisperm antibody production in women. This concept may explain the failure to generate antisperm antibodies in some 30% of the female population (Cunningham DS, Fulgham DL, and Alexander NJ. Unpublished observations). It is difficult to determine how these findings translate into biologic significance because no bioassay exists that can relate antisperm antibody activity to a reproductive event, a determination of postinfection pregnancy rate in this group is as yet uncompleted, and the cause of antisperm antibody responses is not known nor is it understood why responses are not uniform. Even though the details have not been clarified, it is widely accepted that antisperm antibodies, whatever their cause(s), result in a diminished fertility capacity.[6, 12, 13]

We intend to test specific sperm antigens for their immunogenicity in vitro by a panel of lymphocytes from women who have no measurable antisperm antibody activity to facilitate the detection of a meaningful antigen to which to direct monoclonal antibody production. This line of investigation may help in the refinement of antisperm antibody detection methods. Selection of an appropriate screening assay for antisperm antibodies is difficult yet important for both clinicians and researchers. We chose the sperm mixed agglutination reaction test from the variety available[14] for its simplicity and apparent suitability.[1, 5] The accuracy of the test was substantiated when the presence of antisperm antibodies in each positive serum and cervical mucus sample was confirmed by immunoprobe analysis, or the absence of these antibodies was similarly

demonstrated, and when antisperm antibody activity was lost after simple absorption experiments using swim-up sperm or biotinylated sperm surface antigens. Neither a specific antigen(s) nor a superior antibody detection assay exists, although both are requisite to an understanding of the significance of antisperm antibody production and the potential manipulation of the female immune response to spermatozoa for the purpose of infertility reduction and potential immunocontraception.

The expert assistance of Professor Raymond E. Kuhn and Dr. Cheryl D. Davis in immunoblotting techniques, Drs. Randy M. Brodnik and Edward E. Evans in subject recruitment, and manuscript review by Dr. Charles C. Coddington is appreciated.

Genotyping of macerated stillborn fetuses

Catherine Derom, PhD,[a] Robert Vlietinck, MD,[a] Robert Derom, MD,[a] Charles Boklage, PhD,[c] Michel Thiery, MD,[b] and Herman Van den Berghe, MD[a]

Leuven and Ghent, Belgium, and Greenville, North Carolina

It is generally impossible to collect blood or to culture tissue from a macerated stillborn fetus. Accurate genotyping of such a fetus may, however, be critical for the diagnosis of genetic diseases and appropriate genetic counseling. In the East Flanders Prospective Twin Study, placental tissue of twin and triplet sets, in some of which one or both members were stillborn and macerated, has been stored at −20° C. Of all these fetuses, sex and zygosity could be determined accurately on the placental deoxyribonucleic acid. We tested the possibility of nongenetic changes in deoxyribonucleic acid that result from maceration or tissue degradation over time in storage on placental samples from monochorionic twins in which only one member was stillborn and macerated. The deoxyribonucleic acid variants in these monozygotic twins were identical whether or not either cotwin was macerated. Thus deoxyribonucleic acid variants can be determined accurately on the placental tissue of macerated fetuses, even after prolonged freezing. (Am J Obstet Gynecol 1991;164:797-800.)

Key words: Genetic counseling, genotype, stillbirth, twins, zygosity

Recombinant deoxyribonucleic acid (DNA) methods and the analysis of DNA polymorphisms have become increasingly important for carrier detection and prenatal diagnosis of a growing number of genetic diseases.[1] Prenatal diagnosis is possible in the embryo or the fetus because the DNA defect is present in every cell, including those of chorionic villi. Numerous DNA restriction fragment length polymorphisms have now been described. Many of these result from the variable presence of particular restriction enzyme recognition sites giving rise to two or more alleles at each locus.[2, 3] Polymorphism may also be generated by length variation in DNA fragments from hypervariable regions consisting of a variable number of tandem repeats. These regions are often highly informative for genetic analyses because of the multiallelic character of such loci.[4, 5] More recently midisatellite and minisatellite DNA probes have been described which hybridize to many variable numbers of tandem repeats simultaneously, either clustered at a single locus[6, 7] or scattered throughout the genome.[8, 9] Such probes show a highly polymorphic pattern in the population and give rise to restriction fragment length polymorphism patterns that may be unique to the individual (DNA "fingerprints"). All of these types of DNA polymorphisms have been shown to be inherited in mendelian fashion.

VNTR, Variable number of tandem repeats.

DNA can still be extracted from tissues that have been stored for long periods of time.[10] Because we have stored placental tissues from a number of macerated stillborn fetuses, we are able to test the use of placental DNA polymorphisms for their genotyping. Cotwins known to be monozygotic by virtue of monochorionicity, but discordant for stillbirth and maceration, pro-

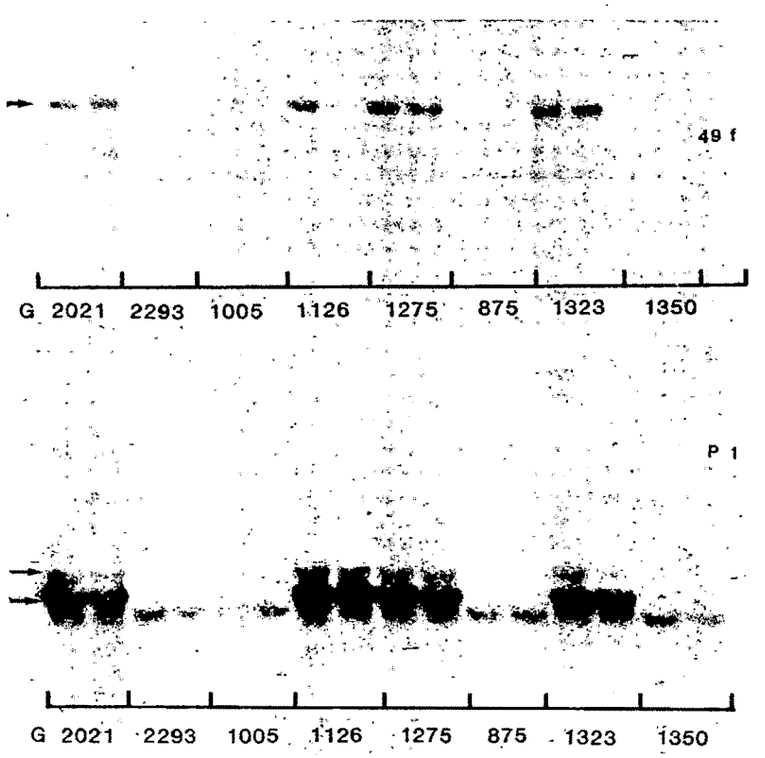

Fig. 1. Hybridization of Y-chromosome-specific probes to the genomic blots of macerated stillborn fetuses. The *Eco*RI blot and the *Hae* III blot were hybridized with the 49f unique sequence probe and the repetitive P1 probe, respectively.[14] Both filters were washed under stringent conditions (0.1 × sodium saline citrate at 68° C). The Y-specific bands are indicated.

vide a unique opportunity to test for any DNA changes resulting from maceration or to any degradation during frozen storage.

Material and methods

The East Flanders Prospective Twin Study was begun on July 1, 1964. To date more than 3300 multiple births are registered.[11] Zygosity diagnosis is based on fetal sex, structure of the fetal membranes, umbilical cord blood groups, placental alkaline phosphatase isozymes, and, more recently, DNA polymorphisms as well. Unlike-sexed twin pairs and same-sexed dichorionic twin pairs with at least one different genetic marker are classed as dizygotic. Monochorionic twin pairs are classed as monozygotic. For same-sexed dichorionic twin pairs with identical markers, we have calculated the probability of monozygosity on the basis of the allele frequency of all tested genetic markers.[12]

The 16 twin pairs and the two triplet sets used for DNA typing in this study were selected at random from the sets in which at least one member was macerated and stillborn. The DNA probes used are described in Table I. PUC15 and PUC6.3 were derived from probes 15.1.11.4 and 6.3, respectively, of Jeffreys et al.[8] Placental DNA extraction, restriction enzyme digestion, and Southern blot hybridization were as previously described.[13] The placental specimens had been stored in a regular freezer (−20° C) for a median time of 7.5 years (range, 8 to 163 months).

Results

Table II summarizes the results of the placental DNA analysis of the macerated stillborn fetuses with the DNA probes listed in Table I. In all of these fetuses the Y-specific probes[14, 15] allowed for the determination of sex (Fig. 1). The influence of tissue degradation on the restriction fragment length polymorphisms was evaluated on the placentas of nine monochorionic twin pairs. In seven of them only one member was a macerated stillborn fetus, so that possible influence of in utero tissue degradation on the restriction fragment length polymorphisms could be detected. The DNA variants and the alkaline phosphatase pattern of monochorionic cotwins were indistinguishable, whether the subjects were stillborn and macerated or living.

Zygosity could be diagnosed as well, i.e., when the

diagnosis relied on the analysis of the placental genetic markers only. The twin pairs G875, G2314, G2710, and the set of triplets T51 proved to be dizygotic and trizygotic, respectively, while the sets G1005, G1556, G1932, G2021, and T58 reached a probability of monozygosity of more than 0.99.

Comment

Even after prolonged freezing the analysis of DNA variants on the placental tissue of macerated stillborn fetuses can be performed accurately. In three cases where sex was unknown at birth because of extreme maceration (child 2 of G1350 and G2247 and child 3 of T51), we were able to determine sex by DNA typing.

Similarly, zygosity diagnosis was obtained in circumstances when, because of maceration, no blood could be sampled for blood group determination, either from the umbilical cord or from other sites.

Given that monozygotic twins have identical restriction fragment length polymorphisms,[9, 13] these analyses performed on monochorionic (therefore monozygotic) twin pairs, one of whom was live-born and the other stillborn and macerated, allow for the demonstration that the placental DNA pattern is identical in the living and macerated cotwins. Placental DNA does not deteriorate detectably after intrauterine death.

With the exception of any somatic mutations and the tissue-specific methylation patterns, the placental and fetal DNA have the same restriction fragment length polymorphisms.[16] Although some authors argue for DNA rearrangements in trophoblast[17] via mitotic recombination, we did not observe any variation in the placental DNA pattern (DNA fingerprints included) of our monozygotic twin pairs.

The use of placental DNA for the genotyping of a macerated stillborn fetus has two main advantages:

1. Placental tissue is very rich in DNA and can be stored at −20° C for a long period of time. If immediate genotyping is not possible or if any unusual DNA variant is found, enough DNA would be available to provide a new standard for this new variant.

2. It is now feasible to use random human chromosome-specific sequences to establish a linkage map for the entire human genome.[18] This should permit diagnosis for many genetic diseases by linkage analysis in the macerated fetus. As more and more loci for genetic diseases become mapped and known, genotyping macerated fetuses is important for diagnosing some of the causes of antenatal death and providing genetic counseling.

We thank Mrs. Rita Desmet for excellent technical assistance.

covering the world

Organons extensive gynaecological product range is esteemed by the medical profession and by innumerable users throughout the world. Similarly, the organisation which develops and supports these products extends world wide. Today Organon includes more than 45 affiliated companies guaranteeing high standards of quality and service.

ORGANON IN GYNAECOLOGY

striving for completeness

Organon

life companion

The rich tradition of gynaecological innovation by Organon research has recently been augmented in the field of hormone replacement therapy. An entirely original medicine has been developed for the post-menopause. This new therapy has been christened 'gonadomimetic'. Again this innovation demonstrates Organon's ability to lead the way in matching innovation with reliability.

The Osler Institute
Obstetrics and Gynecology Review Course
June 3-8, 1991 – Chicago
November 25-30, 1991 – Chicago
for written and oral exams with mock orals and case-list reviews

Co-sponsored by Penn State University

OBJECTIVES
- Increase basic knowledge and clinical skills in ob-gyn.
- Assist residents and fellows to organize study
- Prepare exam candidates to take their tests
- Provide practicing gynecologists with an update

METHODS
- HOME STUDY MATERIALS with questions and answers
- SEMINAR with projection slides and lecture-note syllabus
- LABORATORY with microscope and glass slides
- PRACTICE EXAMS with both oral and written sections

*"The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

*"Accommodations were comfortable...."**

COURSE AND LOCATION: This course for residents and practicing gynecologists is a comprehensive review and update offered in the winter, spring and fall. The fall course is more clinically oriented. Home study questions are sent upon registration. The course includes lectures with syllabus as well as an opportunity to purchase an unlimited number of optional extra one-on-one sessions with faculty to review your case lists or do mock oral exams. Past participants recommend repeating the course for half price immediately before exams. The course will be at the Hilton Inn, 3003 Corporate West Drive, Lisle, Illinois.

*"...and those little extras...."**

LOWEST AIR FARES: Please call toll-free 1-800-548-8185 for group discounts.

*"...the most education for the money."**

FEES FOR 60 CATEGORY 1 HOURS:
- Practicing Gynecologists: $750
- Residents and Fellows: $500
- Repeating course within 2 years: $375
- Case-list reviews and mock oral exams (half hour sessions): $ 70
- Private mock oral exams: $100
- Optional extra day Dec. 1 (more questions, answers and pathology lab): $150
- **Add 10% within 10 days of the course.**
- Attendees not in course hotel add $20/day.
- A deposit of $50 will reserve your position.
- Penn State is accredited by the Accreditation Council for Continuing Medical Education (ACCME) to sponsor continuing medical education for physicians.
  Penn State designates this continuing medical education activity for **60 credit hours** in **Category 1** of the Physican's Recognition Award of the American Medical Association.

*"...home study material was extremely helpful."**

CANCELLATIONS: Refunds, subject to $50 fee, will be made until the seminar begins.

*"...remarkably complete and pleasant."**

A red spot means a lot to a woman.
A red spot may mean breakthrough bleeding

Tri-Levlen® means a low incidence of breakthrough bleeding/spotting*†

Multicenter study demonstrates significantly less breakthrough bleeding/spotting through the first six cycles[1]

P<0.05 for cycles 1,2,3, and 5[1]

n = number of women with a bleeding event occurring during a cycle.

TRI-LEVLEN®

Levonorgestrel and ethinyl estradiol tablets—Triphasic regimen

may mean a lot to a woman

TRI-LEVLEN® 28 Levonorgestrel and ethinyl estradiol
TRI-LEVLEN® 21 tablets–Triphasic regimen

BRIEF SUMMARY
Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxy-gon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage—Tri-Levlen Tablets are indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OCs) as a method of contraception.

Contraindications—OCs should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during the use of OCs or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with the use of OCs is well established. Three principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OCs are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.
CEREBROVASCULAR DISORDERS—In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.
MYOCARDIAL INFARCTION—An increased risk of myocardial infarction associated with the use of OCs has been reported, confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing myocardial infarction, regardless of whether the patient was an OC user or not. OCs, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent.
RISK OF DOSE—In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism, including coronary thrombosis, is directly related to the dose of estrogen used in OCs. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States.
ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES—A large prospective study carried out in the U.K. estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OCs according to age, smoking habits and duration of use. The overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking and duration of use, nor to compare the effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. The available data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. The estimates of risk of death for each method include the combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OCs) plus the risk attributable to pregnancy or abortion in the event of method failure. This latter risk varies with the effectiveness of the contraceptive method. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OCs in women over 40 who smoke. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with OCs increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes or history of preeclamptic toxemia and, especially, by cigarette smoking. The physician and the patient should be alert to the earliest manifestations of thrombophlebitis and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four-to-six-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OCs should be discontinued at least 4 weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization.
PERSISTENCE OF RISK OF VASCULAR DISORDERS—Findings from one study in Great Britain involving cerebrovascular disease and another study in the United States concerning myocardial infarction suggest that an increased risk of these conditions in users of OCs persists after discontinuation of the OC. In the British study, the risk of cerebrovascular disease remained elevated in former OC users for at least six years after discontinuation. In the U.S. study, an increased risk of myocardial infarction persisted for at least 9 years in women 40- to 49-years-old who had used OCs for five or more years. The findings in both these studies require confirmation since they are inconsistent with other published information.
2. *Ocular Lesions:* There have been reports of neuro-ocular lesions, such as optic neuritis or retinal thrombosis, associated with the use of OCs. Discontinue OC medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.
3. *Carcinoma:* Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina and liver. Certain synthetic progestogens, none currently contained in OCs, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case-control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time OCs were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs. Several studies have found no increase in breast cancer in women taking OCs or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with OCs, found an excess risk in the subgroups of OC users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of OCs has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with OCs. Close clinical surveillance of all women taking OCs is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use OCs.
4. *Hepatic Tumors:* Benign hepatic adenomas have been found to be associated with the use of OCs. One study showed that OC formulations with high hormonal potency were associated with a higher risk than lower potency formulations. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of OCs. Two studies relate risk with duration of use of OCs, the risk being much greater after 4 or more years of OC use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women taking OCs. The relationship of these drugs to this type of malignancy is not known at this time.
5. *Use in or Immediately Preceding Pregnancy, Birth Defects in Offspring and Malignancy in Female Offspring:* The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence at the present time that OCs further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OCs. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including OCs, in pregnancy. One case-control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. It is recommended that, for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period and further use of OCs should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue OCs with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.
6. *Gallbladder Disease:* Studies report an increased risk of surgically confirmed gallbladder disease in users of OCs and estrogens. In one study, an increased risk appeared after 2 years of use and doubled after 4 or 5 years of use. In one of the other studies, an increased risk was apparent between 6 and 12 months of use.
7. *Carbohydrate and Lipid Metabolic Effects:* A decrease in glucose tolerance has been observed in a significant percentage of patients on OCs. For this reason, prediabetic and diabetic patients should be carefully observed while receiving OCs. An increase in triglycerides and total phospholipids has been observed in patients receiving OCs. Three studies have been performed with the Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets Triphasic Regimen) formulation and no significant alterations in lipid metabolism were noted, with the exception of a slight increase in triglyceride levels in one study. The clinical significance of these findings remains to be defined.
8. *Elevated Blood Pressure:* An increase in blood pressure has been reported in patients receiving OCs. In some women, hypertension may occur within a few months of beginning OC use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two-and-a-half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given OCs. Hypertension that develops as a result of taking OCs usually returns to normal after discontinuing the drug.
9. *Headache:* The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent or severe, requires discontinuation of OCs and evaluation of the cause.
10. *Bleeding Irregularities:* Breakthrough bleeding, spotting and amenorrhea are frequent reasons for patients discontinuing OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of OCs. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.
11. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.
12. *Breast-feeding:* OCs given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in OCs has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of OCs should be deferred until the infant has been weaned.

Precautions—GENERAL—1. A complete medical and family history should be taken prior to initiation of OCs. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical examination and PAP smear being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. OCs may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving OC therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by OC therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OCs: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

TRI·LEVLEN®
Levonorgestrel and ethinyl estradiol tablets–
Triphasic regimen

Information for the Patient—See Patient Package Labeling
Drug Interactions—Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.
Carcinogenesis—See "Warnings" section for information on the carcinogenic potential of OCs.
Pregnancy—Pregnancy Category X. See "Contraindications" and "Warnings."
Nursing Mothers—See "Warnings."
Adverse Reactions—An increased risk of the following serious adverse reactions has been associated with the use of OCs (see "Warnings"): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies.
There is evidence of an association between the following conditions and the use of OCs, although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.
The following adverse reactions have been reported in patients receiving OCs and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally: gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; dysmenorrhea; amenorrhea during and after treatment; temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement and secretion; change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.
The following adverse reactions have been reported in users of OCs, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.
Acute Overdose—Serious ill effects have not been reported following acute ingestion of large doses of OCs by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.
Dosage and Administration—To achieve maximum contraceptive effectiveness, Tri-Levlen Tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours. (If Tri-Levlen is first taken later than the first day of the first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of administration. The possibility of ovulation and conception prior to initiation of medication should be considered.) Any time the patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another method of contraception until she has taken a tablet daily for 7 consecutive days.
For full details on dosage and administration see prescribing information in package insert. 60611-1 5/86

Weight gain by gestational age in both black and white women delivered of normal-birth-weight and low-birth-weight infants

Diana B. Petitti, MD,[a] Mary S. Croughan-Minihane, PhD,[a] and Robert A. Hiatt, MD, PhD[b]
San Francisco and Oakland, California

Although adequate maternal weight gain during pregnancy is widely acknowledged as a desirable goal, a contemporary standard for weight gain over the entire period of gestation based on a low-risk U.S. population has not been available. Information about usual weight gain in early pregnancy was particularly lacking. In a study monitoring various aspects of prenatal care in women in a population-based case-control study of low birth weight, we collected information on weight gain at various gestational ages in the 281 women who had prenatal care and were delivered of infants at a prepaid health plan facility where standardized records were kept. In white women who were delivered of infants who weighed ≥3000 gm, average weight gain was 5.3 pounds at 9 to 10 weeks' gestation, 10.5 pounds at 11 to 20 weeks, 24.2 pounds at 21 to 30 weeks, and 35.1 pounds at 31 to 40 weeks. Weight gain among black women delivered of infants who weighed ≥3000 gm was 4.2 pounds at 9 to 10 weeks' gestation, 14.8 pounds at 11 to 20 weeks, 24.5 pounds at 21 to 30 weeks, and 33.9 pounds at 31 to 40 weeks. Weight gain was highly variable at all gestational ages in both black and white women. Weight gain in both black and white women delivered of infants with weights ≥3000 gm was linear at a rate of about 0.66 pounds per week from 8 through 20 weeks' gestation and linear at a rate of 1.06 pounds per week after week 20. (AM J OBSTET GYNECOL 1991;164:801-5.)

Key words: Low birth weight, weight gain

Maternal weight gain accounts for the largest proportion of variation in infant birth weight among term infants and the second largest proportion among infants born at all gestational ages.[1] In turn, infant birth weight is strongly associated with infant morbidity and mortality. Although there is general agreement that pregnant women should gain at least 15 pounds, relatively little is known about patterns of weight gain during early pregnancy, and there is no agreement on a standard of weight gain by gestational age. There are a large number of previous studies of maternal weight gain pattern in pregnancy,[1-16] but nearly all[2-14] were conducted during periods of prescribed weight restriction or were conducted in countries other than the United States. Additional limitations of most previous studies are restriction of the study population to poor women, lack of information on sample selection, and failure to consider infant birth weight.

In this study, routine prenatal care records were reviewed to obtain information on prepregnancy weight and weight gain for a group of both black and white middle-class women delivered of low-birth-weight (<2500 gm) and normal weight (≥3000 gm) infants. We used these data to address three questions. First, what is the pattern of weight gain in a group of women delivered of infants under conditions of unrestricted weight gain? Second, does the pattern of weight gain differ between low-risk black women and white women delivered of infants of normal weight? Third, does the pattern of weight gain differ between women delivered of low-birth-weight and normal-birth-weight infants?

Methods

We did a population-based case-control study of low birth weight in Alameda County, California, which has been described previously.[16] Briefly, we used birth certificates to identify both black and white low-birth-weight (<2500 gm) singleton infants without anomaly and an equal number of both black and white singleton infants of normal birth weight (≥3000 gm) born in Alameda County to residents of Alameda County in 1987. There were 500 black patients, 500 black control patients, 268 white patients, and 268 white control patients.

For the current study, we reviewed the medical records of the 308 women among these cases and controls who were delivered of infants at Kaiser Permanente

facilities, where standardized prenatal records are kept and >90% of women attend prenatal care in the first trimester. A single trained medical records abstractor recorded information on prepregnancy weight, the date of each prenatal visit, and maternal weight at each visit. Physicians' estimates of gestational age at the first prenatal visit were used to determine gestational age at each subsequent prenatal visit. Weight gain at each visit was calculated as the difference between weight at a given visit and prepregnancy weight. In the analysis, information on weight gain for all women who attended prenatal care in a given gestational interval was used to calculate the mean weight gain for that interval. If a woman attended prenatal care more than once in an interval, only weight gain at the first visit in the interval was used in the calculation of the mean.

The Student t test was used to assess the statistical significance of differences in weight gain. A probability value of 0.05 was considered statistically significant.

Results

Twenty-four women delivered of infants at a Kaiser Permanente facility were excluded because of inability to retrieve the medical record (n = 12), no prenatal care (n = 7), or prenatal care by a private physician (n = 5). There remained 56 black women and 63 white women delivered of low-birth-weight infants and 101 black women and 61 white women delivered of infants who weighed ≥3000 gm. Four women contributed no information to the analysis because an estimate of either gestational age or prepregnancy weight was missing.

In white women delivered of an infant who weighed ≥3000 gm, mean weight gain was 5.3 pounds at 9 to 10 weeks' gestation, 10.5 pounds at 11 to 20 weeks, 24.2 pounds at 21 to 30 weeks, and 35.1 pounds at 31 to 40 weeks (Table I). Mean weight gain in black women delivered of infants who weighed ≥3000 gm was 4.2 pounds at 9 to 10 weeks' gestation, 14.8 pounds at 11 to 20 weeks, 24.5 pounds at 21 to 30 weeks, and 33.9 pounds at 31 to 40 weeks. None of the differences in weight gain between black women and white women was statistically significant ($p > 0.05$). In both white and

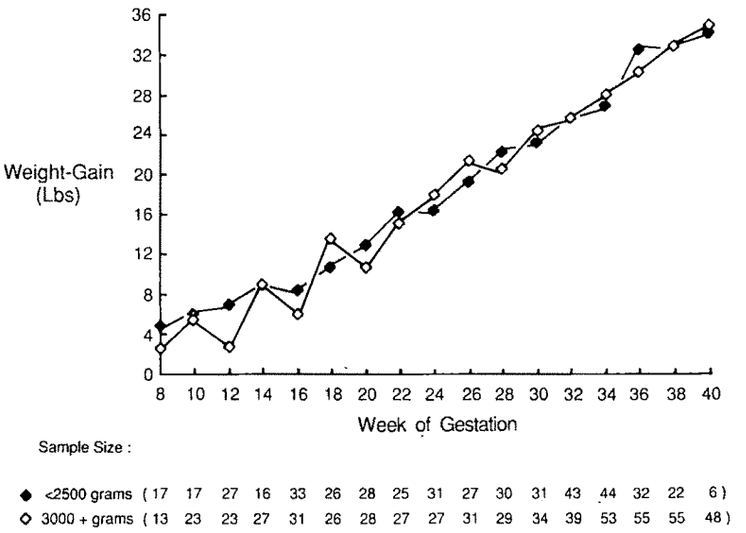

Fig. 2. Weight gain by gestational age in white women delivered of singleton infants who weighed ≥3000 gm, or ≤2500 gm; Alameda County Low Birth Weight Study, Kaiser Permanente subset.

black patients, the SD of weight gain was large at every gestational age. At 31 to 40 weeks' gestation, weight gain ranged from −8 pounds to 89 pounds in white subjects and 4 pounds to 99 pounds in black subjects.

The pattern of weight gain in both black and white women delivered of infants who weighed ≥3000 gm was linear after week 20 (Fig. 1). The rate of weight gain was linear at 1.06 pounds per week after 20 weeks' gestation. The rate of weight gain did not slow in the last 10 gestational weeks.

There was more interval-to-interval variation in average weight gain at earlier rather than at later gestational ages. The appearance of decreasing weight gain in the early gestational intervals is probably a result of the small number of observations in some of these intervals and to the high degree of variability of weight gain relative to the mean. By combining observations from white women and black women delivered of normal-weight infants, one can "smooth" the curve for the period of gestation from weeks 8 through 20. A regression line fitted to these combined data with the use of all data points yields an estimate of the rate of weight gain of 0.66 pounds per week for the interval from 8 through 20 weeks' gestation. Data on weight gain for gestations <7 weeks were so limited that mean weight gain was not calculated.

In white subjects, mean weight gain was essentially the same and not statistically significantly different ($p > 0.05$) at every gestational age in women delivered of low-birth-weight infants compared with those delivered of infants who weighed ≥3000 gm (Fig. 2). In black subjects, mean weight gain in women delivered of low-birth-weight infants was consistently lower than that in women delivered of infants who weighed ≥3000 gm after the 20 weeks' gestation (Fig. 3), although none of these differences was statistically significant ($p > 0.05$).

Comment

Total weight gain in women in our study population was higher than that in other U.S. populations reported in publications during the period 1955 through 1989 (Table II) except that of Abrams and Laros.[17] Total weight gain is higher in more recent studies, suggesting there is a secular trend of higher total weight during pregnancy. A secular trend of greater weight gain would explain the discrepancy between the results of previous studies and both our study and that of Abrams and Laros.[17] The published studies based on pregnancies that occurred in the 1950s and early 1960s encompassed an era when attempts were made to restrict weight gain during pregnancy, and the lower weight gains in these populations may be attributable to this now-abandoned policy. The nonrepresentative nature of previous studies, except that of Taffel,[16] limits the ability to draw a firm conclusion about time trends in weight gain.

A committee of the National Academy of Sciences[18] summarized published studies on weight gain by gestational age. Table III, derived from their report, presents our results along with data on weight gain by week of gestation from the only other studies of well-nourished women with uncomplicated pregnancies reported during 1949 through 1989. Weight gain in U.S. women was higher at every gestational age than that in the British study population. However, the two U.S.

studies are also more recent than the United Kingdom study. Weight gain at comparable gestational ages in the other U.S. study[1] is very similar to weight gain in our population at every gestational age.

We could not identify prior published studies that compared weight gain by gestational age in black women and white women. This is rather surprising because the existence of a 200 to 250 gm difference in birth weight between infants born to black women and white women is well recognized, and the question of differences in pattern of maternal weight gain as an explanation for the difference is an obvious one. In the present study, we found no large difference in mean weight gain between black women and white women delivered of infants who weighed 3000 gm.

Beginning at 20 weeks' gestation, weight gain in black mothers delivered of infants who weighed <2500 gm was less than that in the black women delivered of infants who weighed ≥3000 gm, although the difference was not statistically significant. Even if the difference were significant in a larger sample, the variability of weight gain and the small difference in weight gain between mothers delivered of low-birth-weight and normal-weight infants limits the usefulness of weight gain patterns as a screening tool for identification of women at risk of being delivered of low-birth-weight infants.

Our study has some important limitations. First, the size of the study group is small. This limits the statistical power to find differences in weight gain, although the high variability of weight gain would not be reduced in a larger sample. The small sample size makes examination of modifiers of weight gain, such as prepregnancy weight, unfruitful. Second, we relied on the date of the last menstrual period as recorded at the first routine prenatal visit to estimate gestational age at subsequent prenatal visits. Estimates of gestational age derived in this way are known to be imperfect,[19] although they seem reasonable for term infants, who comprise the majority of our study population. Third, we used the information on weight that was recorded as part of routine prenatal care. Lack of standardization of procedures to record weight and of the timing of prenatal visits may have biased our findings in ways that are unknown.

Several advantages exist for our study population and our methods. The population was largely middle class. Few women experienced prenatal complications, and all women attended regularly scheduled prenatal care appointments. In addition, there was little or no missing information on the variables of interest.

Data from this study were easily obtainable from routine prenatal care records. Further delineation of factors that influenced the pattern of weight gain and identification of the association of pattern of weight gain and pregnancy outcome with routine prenatal care records may be a fruitful area for further research.

In this study the effects of hormone replacement therapy on cardiac function in healthy postmenopausal women were evaluated by Doppler echocardiography that was performed before (T1) and 2.5 months after the initiation of hormone replacement therapy (T2) in the peak estrogenic phase. The following parameters of aortic flow were measured: peak flow velocity, acceleration time, and ejection time. Additional parameters were calculated: flow velocity integral and mean acceleration. The study group included 24 postmenopausal women aged 43 to 60 years (mean 51.6 years). The control group consisted of 19 postmenopausal women aged 46 to 60 years (mean 53.5 years) who were not receiving hormone replacement therapy and who underwent the same evaluation. There were no changes in all Doppler parameters between T1 and T2 in the control group. However, in the study group there were significant increases in peak flow velocity (108.3 ± 16.7 cm/sec at T1 vs 123 ± 20.7 cm/sec at T2; $p = 0.002$), flow velocity integral (17.7 ± 3.9 vs 21.5 ± 4.7 cm; $p = 0.0003$), mean acceleration (11.5 ± 1.9 vs 13.1 ± 2.6 m/sec/sec; $p = 0.001$), and ejection time (324 ± 37.6 vs 348.8 ± 40.7 msec; $p = 0.002$). There was no change in acceleration time (94.8 ± 6.6 vs 95 ± 10.9 msec). These results demonstrate that estrogens increase both stroke volume and flow acceleration. The latter probably reflects a combination of enhanced inotropism and vasodilatation. We assume that the cardioprotective effect of hormone replacement therapy in postmenopausal women may be due not only to changes in lipid profile but also to direct effects of estrogens on central and peripheral hemodynamic parameters. (Am J Obstet Gynecol 1991;164:806-12.)

Key words: Menopause, hormone replacement therapy, aortic blood flow, Doppler echocardiography

During the past 10 years there has been a growing interest in estrogen replacement therapy for postmenopausal women.[1, 2] The effects of estrogen replacement therapy in this population have been studied extensively, and changes that have been induced by estrogens in the genitourinary system, bone, and liver and in major metabolic pathways have been well documented. It has been known since the beginning of this century that estrogens also exert hemodynamic changes through several different mechanisms.[3, 4] Plasma volume, stroke volume, and cardiac output were found to increase, and peripheral resistance was found to decrease in women who were taking oral contraceptives, during pregnancy, or during the normal menstrual cycle, correlating with the elevation of estrogen levels. However, information on hemodynamic effects of estrogen replacement therapy in postmenopausal women is scarce.[5]

Several reports have discussed the nonspecific electrocardiographic ST-T changes that are induced by estrogens, which resemble those that are induced by digoxin and which in fact provide indirect evidence for the influence of estrogens on the myocardium.[6] Evidence for a direct effect of estrogens on heart muscle was obtained in animal studies. These included the identification of physiologically functioning estrogen receptors in the heart and aorta[7, 8] and changes in myosin-adenosinetriphosphatase and lysosomal enzyme activities after estrogen deprivation or supplementation.[9] In view of these data in humans and animals, we decided to evaluate several Doppler-derived

parameters in postmenopausal women who were receiving hormone replacement therapy.

Patients and methods

During a 2-month period, all women who were referred for consultation at the Menopause Clinic were asked to participate in the study. Postmenopausal state was established by serum estradiol levels of less than 20 pg/ml and follicle-stimulating hormone levels of at least 30 mIU/ml. Exclusion criteria were: age over 60 years, hypertension, diabetes mellitus (or any other endocrinopathy) or treatment with medications that might affect cardiac function. Also excluded were patients with heart disease (on the basis of physical examination, past history, and electrocardiographic results). The remaining women were divided into two groups according to the decision of whether or not to recommend hormone substitution with a sequential regimen of combined estrogen-progesterone treatment. The study group, which was receiving hormone replacement therapy, was evaluated by Doppler echocardiography before treatment (T1) and in the middle of the third cycle of hormone replacement therapy (T2), in the peak estrogenic phase and at least 2 weeks after treatment with progesterone of the previous hormonal cycle. The control group, which was not receiving hormone replacement therapy, also had two sets of Doppler examinations at similar time intervals.

Doppler technique. Examinations were performed with a wide-angle phased-array Hewlett Packard Sonos 500 imaging system (Hewlett Packard Co., Medical Products Gr., Andover, Mass.) with a pulsed Doppler transducer. Doppler studies were performed from the suprasternal notch, and the ascending aorta was interrogated. The sample volume depth was gradually adjusted until the optimal flow pattern that showed the highest velocity with the least spectral dispersion was found. The axial size of the sample was 5 mm.

Sample size, spectral depth, and position in the vessel remained constant throughout the study. Before the examination of each patient, the Doppler echocardiography operator familiarized himself or herself with the optimal window and angulation for the subject and also made the necessary adjustments in the equipment. Measurements were taken from frozen images and averaged 5 beats for each examination.

Doppler examinations were done at a speed of 100 mm/sec and taped on a commercial Panasonic AG-6200 videotape recorder (Matsushita Electric Corp. of America, Seacaucus, N.J.). The images were replayed for analysis in real-time, slow-motion, and freeze-frame modes, and they were reviewed independently by two observers who were unaware of the subjects' clinical data.

Doppler measurements. Peak flow velocity, expressed in centimeters per second, was defined as the midpoint of the upper portion of the Doppler signal at the time of maximal velocity. Ejection time, expressed in milliseconds, was defined as time from onset until end of systolic flow; both points were determined by the time at which the Doppler signal crossed the zero-flow line. Acceleration time, expressed in milliseconds, was defined as the time from onset of flow to peak velocity point. Mean acceleration was calculated as peak flow velocity/acceleration time and expressed in meters per second per second. The flow velocity integral, which represents the area under the systolic portion of the velocity signal, reflects the forward distance that is traveled by the erythrocytes during a given systole. After delineation of the contour of the signal with the joystick, the flow velocity integral was internally derived by the system on the basis of planimetric integration of the pixels that were included in the flow envelope, and it was expressed in centimeters.

Statistical analysis. Values were expressed as mean ± standard deviation. The percent change in Doppler-derived parameters of aortic flow was calculated as (T2 value − T1 value)/T1 value. For comparisons between T1 and T2 data within the groups we used Student's two-tailed t test for paired observations, whereas for intergroup comparisons we used the unpaired t test. A p value of <0.05 was considered significant.

Results

The study group included 24 women, aged 43 to 60 years (mean 51.6 ± 3.9 years), 21 (87.5%) of whom had natural menopause. The mean time from menopause was 40 ± 42 months. The control group consisted of 19 women, aged 46 to 60 years (mean 53.5 ± 4.4 years), 15 (78.5%) of whom had natural menopause. Time from menopause was 52 ± 48 months. The average weight for the control group exceeded that of the study group at the baseline value (67.9 ± 10.4 vs 61.1 ± 10 kg, $p = 0.04$); however, weight did not change significantly in both groups from T1 to T2. Blood pressure and heart rate were similar in both groups at T1 and T2. Hormone replacement therapy consisted of conjugated estrogens 0.625 mg for 12 days combined with medroxyprogesterone acetate 5 mg over the following 13 days (Premaril plus, Dexxon, Herzliya, Israel) in 17 women and skin patches of estradiol 4 mg, which were applied twice a week (Estraderm Transdermal System 50, Ciba Pharmaceutical Co., Summit, N.J.) combined with oral medroxyprogesterone acetate 5 mg (Aragest, Dexxon) on days 13 to 22 of each cycle in seven women.

Doppler measurements. Diagnostic quality suprasternal Doppler images were obtained in all subjects. The intraobserver variability was 3.2% for peak flow velocity, 2.2% for ejection time, and 3.0% for acceleration time. The interobserver variability was 3.5% for peak flow velocity, 2.4% for ejection time, and 2.9% for

PMW, Postmenopausal women; *HRT*, hormone replacement therapy; *PFV*, peak flow velocity; *NS*, not significant; *FVI*, flow velocity integral; *AT*, acceleration time; *ET*, ejection time; *MA*, mean accelerations.

*Percent change = value of (T2 − T1)/T1 × 100.

acceleration time. None of these differences were significant. The aortic valve dimensions remained unchanged at T1 and T2.

The mean measured values of peak flow velocity and acceleration time at T1 were higher for the control group than for the study group (120.2 vs 108.3 cm/sec, $p = 0.02$; 99.2 vs 94.8 msec, $p = 0.04$) (Table I). There was no difference between the groups regarding ejection time (324 vs 321.1 msec). The calculated flow velocity integrals of the control group at baseline were thus higher than those of the study group, although they did not reach statistical significance (19.4 vs 17.7 cm, $p = 0.067$). These differences in T1 could reflect the greater weight of women in the control group, since stroke volume is positively correlated with body weight.

The study group showed very significant increases ($p < 0.001$) in peak flow velocity, flow velocity integral, ejection time, and mean acceleration from T1 to T2 (Table I and Figs. 1 to 6), but acceleration time did not change. Peak flow velocity and flow velocity integral decreased in five women only, ejection time was reduced only in three, and acceleration time was reduced in seven. In spite of more prominent intragroup variations in all parameters in the control group, there was no change in any of the parameters from T1 to T2 for that group as a whole.

In a comparison of the percent change of the above variables from T1 to T2, both groups showed similar results (Table I). In the study group the peak flow velocity increased by a mean of 17.4%, the flow velocity integral by 25.8%, ejection time by 8.3%, and mean acceleration by 15.4%. The corresponding mean changes in the control group were 4.4% ($p = 0.02$), 3.9% ($p = 0.001$), 1.6% ($p = 0.03$), and 4.1% ($p = 0.066$). Acceleration time changed by only 0.6% in the study group and by only 0.5% in the control group. A review of the echocardiographic results in women who

were taking Premaril plus versus women who were taking Estraderm Transdermal System 50 showed that there was no differences between the groups in all of the parameters that were tested.

Comment

The incidence of coronary artery disease in premenopausal women is lower when compared with age-matched men but increases rapidly after menopause. This observation suggested that estrogens have cardioprotective properties.[2, 10] Long-term epidemiologic studies of postmenopausal women who were receiving estrogen replacement therapy revealed a significant decrease in cardiovascular morbidity and mortality rates.[10-12] The cardioprotective effect of estrogen replacement therapy was attributed mainly to beneficial alterations in lipid profile,[13] but other pathophysiologic mechanisms probably exert an additional protective effect. In the present study we examined, by Doppler echocardiography, the possible effects of hormone replacement therapy on aortic flow.

Our main observations were highly significant increases in peak flow velocity, flow velocity integral, and mean acceleration after 2.5 months of hormone replacement therapy. Some of these findings are in accord with previously published echocardiographic data on

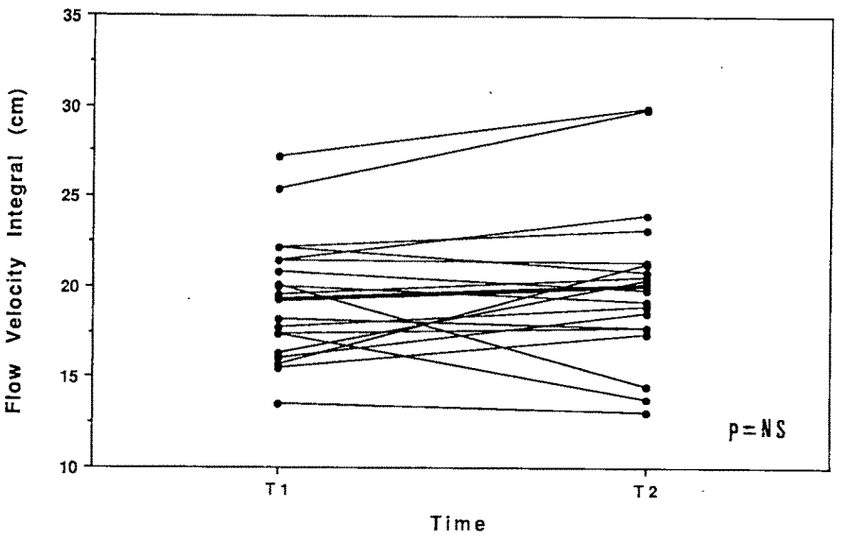

Fig. 4. Flow velocity integral values in control group (N = 19) at beginning (T1) and termination (T2) of study.

women in hyperestrogenic states,[14-18] although one must note that hormone levels in women who are receiving hormone replacement therapy are very low compared with those in any of the following conditions: Mashini et al.,[14] with the use of the M-mode technique to monitor stroke volume and ejection fraction throughout pregnancy, found an increase in cardiac output, which they attributed to a higher heart rate and a lower systemic vascular resistance. Robson et al.[15] compared cardiac output as determined by the Fick technique with Doppler measurements of three valve flows in pregnant and nonpregnant women. They found that measurements at the aortic valve provided the closest concordance with cardiac output as determined by the Fick method. La Sala et al.[16] investigated the cardiovascular adaptation to rapid increase of estrogen levels during multiple follicular stimulation, late luteal phase, or early pregnancy. With two-dimensional and Doppler echocardiography, they demonstrated an increase in cardiac index and in left ventricular end-systolic and end-diastolic dimensions and a decrease in systemic vascular resistance. They also showed that these hemodynamic modifications occurred within less than 2 weeks after the acute changes in estrogen levels. Vielle

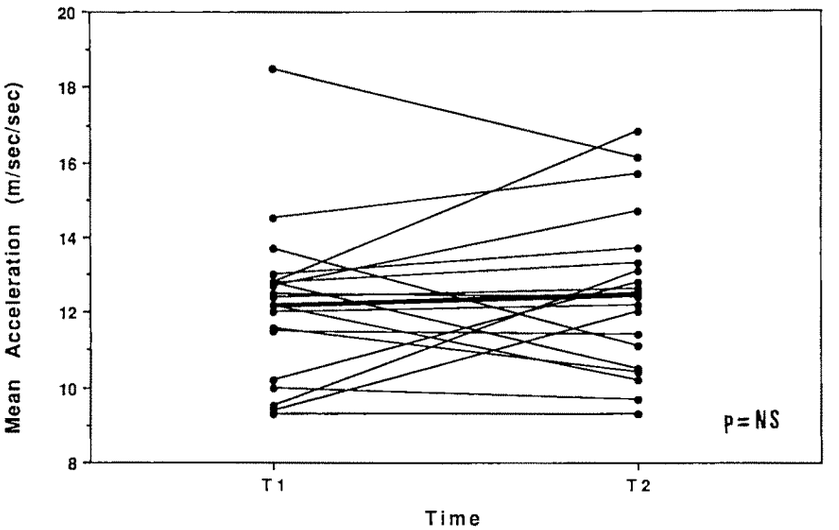

Fig. 6. Mean acceleration values in control group (N = 19) at beginning (T1) and termination (T2) of study.

et al.[17] evaluated changes during ovulation induction by M-mode echocardiography. They found significant increases in left ventricular diastolic dimension, stroke volume, and cardiac index, which were accompanied by a concomitant decrease in systemic vascular resistance. These changes were evident within a week and paralleled serum estrogen levels. Kessler et al.[18] compared echocardiographic parameters of left ventricular size and function in young women who were and who were not taking oral contraceptives. No differences between these groups were observed in any of the measured parameters.

The increase in flow velocity integral, which parallels an increase in stroke volume (stroke volume = flow velocity integral × aortic valve area), was therefore expected in our treated patients. The observed increase in mean acceleration deserves special attention. Acceleration is not influenced by preload and only marginally affected by heart rate.[19] In fact, it has been shown that flow acceleration is a useful index of myocardial contractility, which correlates well with ejection fraction.[20] It is also very sensitive to changes in the contractile state.[19] Hence the increase in mean acceleration might reflect a positive inotropic effect of estrogens. In fact, such an effect could be expected on the basis of the structural similarity of estrogens and digoxin. Furthermore, animal studies[21] have suggested that estrogens may upregulate the density of both muscarinic and β-adrenergic cardiac receptors and thus contribute to enhanced contractility. Further studies are obviously needed to establish a direct inotropic effect of estrogens in human and to evaluate the possible role of such an effect on cardiovascular morbidity. In conclusion, measurement of parameters of aortic flow by Doppler echocardiography showed that hormone replacement therapy in postmenopausal women is associated with an increase in stroke volume and flow acceleration. Since menopause carries a potentially higher risk for cardiovascular morbidity and since hormone replacement therapy is now strongly recommended for the majority of postmenopausal women, it is crucial to further evaluate all potential effects of such therapy on the cardiovascular system.

We thank Ms. Sima Shaer for her assistance in performing the echocardiographic examinations.

Decreased levels of polyunsaturated fatty acids in preeclampsia

Yuping Wang, MD, Helen H. Kay, MD, and Allen P. Killam, MD
Durham, North Carolina

Plasma levels of polyunsaturated fatty acids in the *n*-3 and *n*-6 classes, which include linoleic, linolenic, arachidonic, eicosapentaenoic, and docosahexaenoic acids, were quantified with high-performance liquid chromatography in nonpregnant volunteers and in patients with normal pregnancies or preeclampsia at term. The total polyunsaturated fatty acid levels were not significantly different between nonpregnant and normal pregnant patients but was significantly lower in the preeclamptic patients compared with normal pregnant patients. This decreased level could represent altered fatty acid metabolism or altered storage and mobilization from lipid pools. Compared with nonpregnant patients, normal pregnant patients had significantly higher levels of eicosapentaenoic and docosahexaenoic acid. This may reflect normal physiologic changes in pregnancy, and the decreased level of eicosapentaenoic acid seen in preeclamptic patients may play a significant role in the pathophysiology of preeclampsia. (Am J Obstet Gynecol 1991;164:812-8.)

Key words: Preeclampsia, polyunsaturated fatty acids, high performance liquid chromatography

The prostanoids thromboxane and prostacyclin have been of special obstetric interest over the past few years, since preeclampsia may be related to an imbalance in prostacyclin and thromboxane production.[1, 2] Prostacyclin is a potent vasodilator and thromboxane is a potent vasoconstrictor. The importance of these substances extends our interest to the entire group of polyunsaturated fatty acids, some of which are precursors to these prostanoids (Fig. 1). The two main classes of polyunsaturated fatty acids that have been the focus of clinical attention are the *n*-6 and *n*-3 classes. Linoleic acid is the main precursor of the *n*-6 class, and linolenic acid is the precursor of the *n*-3 class. Both these acids are essential fatty acids because humans cannot synthesize them and therefore must ingest them in the diet. Linoleic acid is the immediate precursor to arachidonic acid which is converted by cyclooxygenase to the prostanoids, which include prostacyclin and thromboxane. Arachidonic acid is also converted by lipooxygenase to leukotrienes. Linolenic acid is the precursor

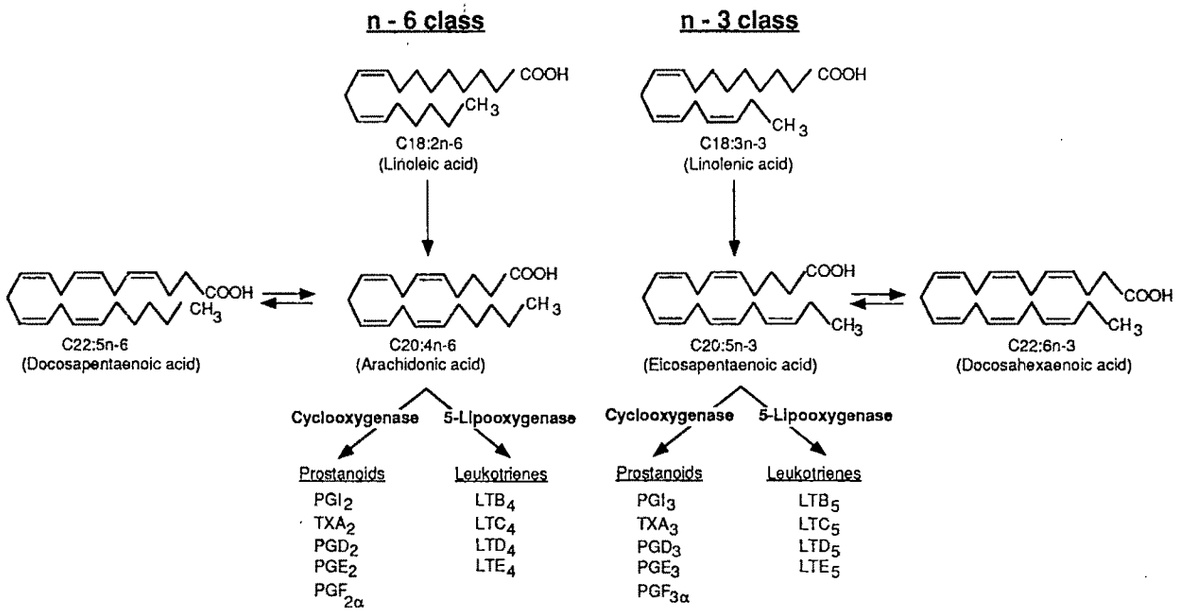

Fig. 1. Metabolic pathways of *n*-3 and *n*-6 polyunsaturated fatty acids.

of eicosapentaenoic acid, which is then reversibly converted to docosahexaenoic acid. Eicosapentaenoic acid is also metabolized by cyclooxygenase and lipooxygenase to different prostanoids and leukotrienes with biologic properties different from those derived from arachidonic acid.[3]

Other investigators have previously noted a relationship of polyunsaturated fatty acids to the control of hypertension. Bang et al.[4] reported in the mid 1970s that Eskimos in Greenland who had a low mortality from myocardial infarction ate a diet high in polyunsaturated fats. Their diet, which primarily consists of fish, is rich in *n*-3 polyunsaturated fatty acids. Subsequently, several randomized, placebo-controlled clinical studies of hypertensive patients have demonstrated a beneficial effect of fish oil in reducing blood pressure, suggesting that the *n*-3 class of polyunsaturated fatty acids, particularly eicosapentaenoic acid, plays an important role in regulating vascular disease.[5] It is thought that a diet high in these fatty acids can decrease effective thromboxane and increase effective prostacyclin production and therefore correct an underlying imbalance between these agents. These fatty acids are capable of reducing triglyceridemia, cholesterolemia, and platelet aggregation, all of which may lower the incidence of atherosclerotic disease.[6] Additionally, these fatty acids can decrease blood viscosity, increase erythrocyte deformity, and increase antithrombin levels.

The relationship between the *n*-3 and *n*-6 classes of fatty acids has not been well studied in pregnancy. Eicosapentaenoic acid is capable of reducing prostacyclin and thromboxane A_2, because its derivatives, prostaglandin I_3 and thromboxane A_3, can compete with arachidonic acid for cyclooxygenase activity.[7] An interrelationship between *n*-3 and *n*-6 fatty acids may represent normal regulatory mechanisms for the maintenance of vascular tone. The effects of arachidonic acid–derived prostanoids in preeclampsia may be regulated by prostanoids derived from eicosapentaenoic acid in the *n*-3 class of fatty acids. The purpose of this study was to further elucidate the relationships between these two classes of polyunsaturated fatty acids by investigating the levels of *n*-6 (linoleic acid and arachidonic acid) and *n*-3 (linolenic acid, eicosapentaenoic acid, and docosahexaenoic acid) fatty acids in nonpregnant, normal pregnant, and preeclamptic patients.

Material and methods

Blood samples were obtained from nonfasting volunteers and patients after they had given informed consent. Subjects were all between 20 and 40 years of age and included 11 normal pregnant patients, 9 preeclamptic patients, and 10 nonpregnant female volunteers as controls. Preeclampsia was defined as blood pressure ≥140/90 mm Hg on two separate readings at least 6 hours apart, proteinuria, and edema. All normal and preeclamptic patients were at term, and none had been on a regimen of aspirin therapy before entering the study. The control group subjects were not using oral contraceptives. Blood samples were drawn into ethylenediaminetetraacetic acid Vacutainer blood-collecting tubes (Becton-Dickinson, Rutherford, N.J.). The plasma was separated by centrifugation at

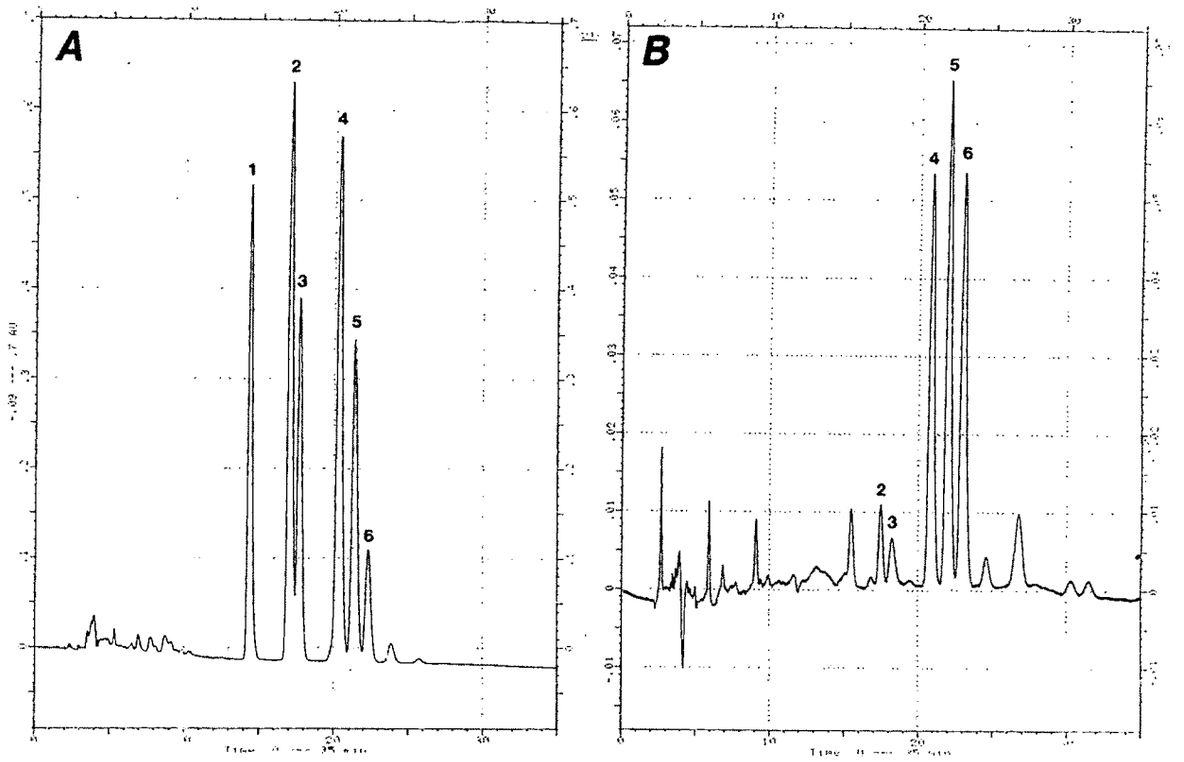

Fig. 2. A, Chromatogram of six polyunsaturated fatty acid standards. Only five were pertinent to our current study. Note clean separation of peaks. *1,* Octadecatetraenoic acid; *2,* eicosapentaenoic acid; *3,* linolenic acid; *4,* docosahexaenoic acid; *5,* arachidonic acid; *6,* linoleic acid. **B,** Chromatogram of plasma sample from study subject showing five fatty acids of interest in current study. *2,* Eicosapentaenoic acid; *3,* linolenic acid; *4,* docosahexaenoic acid; *5,* arachidonic acid; *6,* linoleic acid.

1000 rpm for 10 minutes and stored at −20° C until analysis was performed.

Fatty acids were analyzed by high-performance liquid chromatography carried out on a gradient system (Waters model 600E, Millipore Corp., Milford, Mass.) equipped with a guard column PR 8 or PR 4 (Brownlee Lab, Inc., Santa Clara, Calif.) and reversed phase column of octyl (particle size 5 μm, 10.0 mm × 2.5 cm inner diameter, Beckman Instruments, Inc., Fullerton, Calif.) linked in series. The separation of the methyl ester derived fatty acid mixture was carried out using methanol/water (90:10, vol/vol) as a mobile phase at a flow-rate of 3 ml/min. The eluent was monitored by a photodiode array detector (model 990, Water Dynamics). The wavelength was set at 210 nm. The liquid chromatography system was linked with a computer (Power Mate II, NEC, Tokyo).

Standards consisting of linoleic acid methyl ester, arachidonic acid methyl ester, linolenic acid methyl ester, 5,8,11,17-eicosapentaenoic acid methyl ester, and *cis*-4,7,10,13,16,19-docosahexaenoic acid ester were purchased from Sigma (St. Louis). No standard was available for docosapentaenoic acid; therefore it was not assayed. Acetyl chloride, methanol, and potassium carbonate anhydrous were purchased from Fisher Scientific Company (N.J.). Methyl alcohol of high-performance liquid chromatography reagent grade was obtained from Mallinckrodt (Paris, Ky.). All chemicals and solvents were of analytic reagent grade. Deionized and distilled water was used.

Fatty acids were measured in their methyl ester form. The methylation method was described by Lepage and Roy.[8] Briefly, 150 μl plasma was added to 5 ml of methanol/acetyl chloride (50:1, vol/vol), thoroughly mixed, and left at room temperature for 45 minutes. The methylation reaction was stopped by the slow addition of 3 ml of 6% potassium carbonate solution to the mixture. After 5 minutes, 1 ml of hexane was added and the mixture was vigorously shaken. The hexane layer, which contained the methylated fatty acids, was separated and dried under nitrogen. The residue was dissolved in acetonitrile for lipid analysis of high-performance liquid chromatography. A typical chromatogram obtained with a mixture of six polyunsaturated fatty acid standards is shown in Fig. 2, *A*, and one of a plasma sample is shown in Fig. 2, *B*. The

Table I. Plasma polyunsaturated fatty acid levels

	Nonpregnant (n = 10) (mg/L, mean ± SE)	*Normal pregnant (n = 11) (mg/L, mean ± SE)*	*Preeclampsia (n = 9) (mg/L, mean ± SE)*
Total polyunsaturated fatty acids	79.51 ± 3.47	90.60 ± 6.68 ($p < 0.05$)*	67.42 ± 3.88
Linoleic acid (18:2 *n*-6)	60.79 ± 2.28	62.93 ± 4.69 ($p < 0.01$)*	45.98 ± 2.80
Arachidonic acid (20:4 *n*-6)	10.99 ± 1.01	12.81 ± 0.87	11.44 ± 1.00
Linolenic acid (18:3 *n*-3)	1.88 ± 0.17	3.68 ± 0.99 ($p < 0.05$)*	1.11 ± 0.25

*Normal pregnant versus preeclampsia.
†Nonpregnant versus pregnant.

individual fatty acids yielded single discrete peaks in the chromatogram. The methyl ester derivatives of the five plasma polyunsaturated fatty acids of interest could be separated within 30 minutes. All peaks of the polyunsaturated fatty acids in the methyl ester form were identified on the basis of their retention times and wavelengths of the eluents in comparison with the standard compounds.

Standard curves derived from plotting peak integrals were prepared for each fatty acid, and linearity was established within the lower and upper limits of detection. The correlation coefficients of the standard curves were: linoleic acid, 0.999; arachidonic acid, 1.000; linolenic acid, 0.999; eicosapentaenoic acid, 0.995; and docosahexaenoic acid, 0.999: To test our recovery of the fatty acids, varying amounts of free arachidonic acid were added to five plasma samples before methylation and analysis with high-performance liquid chromatography, as described above. Recovery of the added arachidonic acid was 98%.

Since levels of fatty acid precursors and derivatives might be influenced by food intake, two nonpregnant and two normal pregnant volunteers were tested while fasting and 2 hours after eating.

Statistical analysis comparing mean levels between nonpregnant and normal pregnant patients and between normal pregnant and preeclamptic patients was performed with the Student *t* test. A p value <0.05 was considered to be significant. Regression analysis was used to establish standard curves.

Results

A comparison of the mean serum concentrations of polyunsaturated fatty acids between nonpregnant and normal pregnant subjects and between normal pregnant and preeclamptic patients is presented in Table I. The total polyunsaturated fatty acids in the normal pregnant group was not significantly higher than in the nonpregnant patients but was significantly higher than in preeclamptic patients ($p < 0.05$). In the *n*-6 group of fatty acids, there was a significant difference between the plasma levels of linoleic acid in normal pregnancy compared to preeclampsia ($p < 0.01$), but there was no difference between normal pregnant patients compared with nonpregnant individuals. There were no significant differences in the arachidonic acid levels among any groups.

In the *n*-3 group of fatty acids, a significant difference was noted between the levels of linolenic acid in normal pregnant and preeclamptic patients ($p < 0.05$), but there was no statistical difference between the nonpregnant and normal pregnant patients. There were significant increases of eicosapentaenoic acid and docosahexaenoic acid in normal pregnant patients compared with nonpregnant patients. Although eicosapentaenoic acid was significantly lower in the preeclamptic patients than in the normal pregnant patients, there was no significant difference in docosahexaenoic acid levels between the two groups.

No statistical differences were noted in the five polyunsaturated fatty acid levels between fasting and nonfasting states in both nonpregnant and normal pregnant subjects (Table II).

Comment

Our current study is the first to report levels for several different polyunsaturated fatty acids in normal pregnancy and in preeclampsia. We found that the total level of the five plasma polyunsaturated fatty acids we studied were decreased in the preeclamptic patients compared with normal pregnant patients, but there was no difference between the levels in nonpregnant and normal pregnant patients. There is very little data, if any, in the published literature on plasma levels and

Table II. Fasting and postprandial polyunsaturated fatty acid levels

	Nonpregnant (mg/L)		*Normal pregnant* (mg/L)*	
	Subject 1	*Subject 2*	*Subject 3*	*Subject 4*

*Normal pregnant volunteers were in the second trimester of pregnancy and therefore levels may differ from those observed in Table I in individuals at term.

clinical significance of the *n*-3 and *n*-6 classes of polyunsaturated fatty acids in normal or preeclamptic patients. Ogburn et al.[9] reported arachidonic acid levels that were higher than ours, but this most likely reflects the difference in method. One other group[10] reported that preeclamptic patients demonstrated an increased ratio of a diene conjugated isomer of linoleic acid to its nonisomerized form, as measured in our study. The fact that this ratio was increased suggests that the nonisomerized form of linoleic acid is decreased in preeclampsia, which is directly consistent with our current findings.

The lower level of plasma fatty acids seen in preeclamptic patients is not completely understood. A dietary deficiency has been suggested by investigators who noticed a higher incidence of preeclampsia in women from lower socioeconomic classes who had poor nutritional status. Another explanation may be a decreased fatty acid absorption from the gastrointestinal tract. Both of these possibilities are less likely because the body contains a large pool of essential fatty acids, and clinical deficiency states are rare in adults.[11]

Another more likely explanation for the reduced levels of plasma fatty acids may be altered metabolism in preeclamptic patients, resulting in more rapid conversion of linoleic and linolenic acids to their metabolites. The relatively low level of eicosapentaenoic acid suggests that it may also be more quickly metabolized to prostanoids and leukotrienes via the cyclooxygenase/lipooxygenase pathways, or to docosahexaenoic acid. Additional studies on both the levels and the roles of the metabolites should be informative. At present, there is little information on the lipooxygenase-dependent pathways and the role of docosahexaenoic acid.

One last possible explanation for the decreased plasma levels of polyunsaturated fatty acids in preeclampsia in this study may be altered storage and mobilization of these fatty acids, i.e., there may be increased incorporation of fatty acids into cell membrane phospholipids or a decreased release of fatty acids from lipid storage pools. Under normal conditions it is known that eicosapentaenoic acid and arachidonic acid are rapidly incorporated into platelet and endothelial cell membrane phospholipids.[11, 12] In disease conditions such as preeclampsia, a disequilibrium in the uptake and mobilization of such fatty acids from their storage pools may be an important pathophysiologic feature.

Arachidonic acid levels were not significantly different among any of the three groups studied and, since linoleic acid is low in the preeclamptic group, there could be increased metabolism of linoleic acid to arachidonic acid in that group. This is important since linoleic and arachidonic acids are the precursors to thromboxane and prostacyclin. Ogburn et al.[9] also reported no difference between the arachidonic acid levels of normal pregnant and preeclamptic patients. A decrease in the plasma arachidonic acid levels therefore do not appear to be responsible for manifestations of preeclampsia. Instead, these findings support other suggestions that the rate of production of a metabolite

may be more predictive of disease than the actual amount of the metabolite.[13] Recent studies have supported the use of aspirin to prevent preeclampsia by inhibiting cyclooxygenase conversion of arachidonic acid to thromboxane.[14] Decreasing thromboxane synthesis in this manner may counterbalance altered production of arachidonic acid in preeclamptic patients and restore the balance between prostacyclin and thromboxane.

The most significant difference in the *n*-3 class was noted in eicosapentaenoic acid, which is increased in the plasma of normal pregnant patients compared with that of nonpregnant patients but is significantly decreased in preeclamptic patients when compared with normal pregnant patients. Docosahexaenoic acid is also higher in normal pregnant patients. These two fatty acids play a significant role in regulating vascular activity via several mechanisms.[3] First, they can inhibit the synthesis of arachidonic acid from linoleic acid by competing for cyclooxygenase activity. Second, they can compete with arachidonic acid for incorporation in the 2-position in membrane phospholipids, reducing plasma and cellular levels of arachidonic acid.[12] Third, eicosapentaenoic acid competes with arachidonic acid as a substrate for cyclooxygenase activity and inhibits production of physiologically active thromboxane A_2 in platelets while producing only small amounts of thromboxane A_3, which is less of a platelet aggregator than thromboxane A_2.[15, 16] Thus in normal pregnant patients an increase in the levels of eicosapentaenoic acid and docosahexaenoic acid, as demonstrated in this study, may represent a normal physiologic response to pregnancy. In contrast, a reduced level of eicosapentaenoic acid in the preeclamptic women can cause altered vasodilatory control by significantly altering arachidonic acid synthesis and metabolism which, in turn, directly affects synthesis and metabolism of thromboxane. Eicosapentaenoic acid is also a precursor to prostanoids such as PGI_3, which are known vasodilators, and reduced levels of eicosapentaenoic acid could lead to more vasoconstriction and platelet aggregation.

Increasing the dietary intake of the *n*-6 and *n*-3 precursors during pregnancy, such as by taking fish oil supplements, may correct deficiencies or imbalances between different fatty acids and might ameliorate clinical manifestations of preeclampsia, just as it has in chronic essential hypertension. Our current results lend support to such therapy. Since it has been suggested that preeclampsia is an endothelial cell dysfunction with cell damage that can bring about a cascade of events resulting in coagulopathy and vasoconstriction,[17] fish oil supplements rich in *n*-3 fatty acids may be beneficial by decreasing platelet aggregation, reducing triglyceride levels to prevent triglyceride accumulation, which damages endothelial cells, and by increasing antithrombin levels. If preeclampsia is, in fact, a failure of trophoblast infiltration of the spiral arteries,[18] then dietary modifications begun in early pregnancy or before conception may modify the course of the disease. Although low-dose aspirin therapy has no known adverse fetal or adult effects,[19] therapy by dietary manipulation could be safer, particularly in the first trimester.

Additional studies are needed to define the roles of *n*-3 and *n*-6 polyunsaturated fatty acids in normal and preeclamptic pregnancies and, in particular, their effects on endothelial cell functions. At the present time, it is uncertain if the *n*-3 or the *n*-6 class of fatty acids is the more important in the pathophysiologic composition of preeclampsia. It is also uncertain if changes in the levels in either class are the cause of the disease, a sign of the disease, or a reflection of yet another metabolic imbalance.

Amniotic fluid glucose and intraamniotic infection

Brian Kirshon, MD, Bernard Rosenfeld, MD, Giancarlo Mari, MD, and Michael Belfort, MD

Houston, Texas

Thirty-nine patients with either premature labor and/or preterm premature ruptured membranes underwent transabdominal amniocentesis to enable the following amniotic fluid analyses to be performed: culture and sensitivity, Gram's stain, and glucose determination. All nine patients with intraamniotic infection had amniotic fluid glucose values <10 mg/dl. Three patients with amniotic fluid glucose levels <10 mg/dl but without chorioamnionitis were delivered of infants within 72 hours of admission. The mean amniotic fluid glucose level of patients with intraamniotic infection (5 ± 2.4 mg/dl) was significantly lower than in those without intraamniotic infection (39.8 ± 18.42 mg/dl). All patients with amniotic fluid glucose values <10 mg/dl had either bacteria and/or white glood cells on Gram's stain. Two patients without chorioamnionitis had white cells on Gram's stain and amniotic fluid glucose values >10 mg/dl. It appears that amniotic fluid glucose is more sensitive and more specific than Gram's stain in the diagnosis of intraamniotic infection. All 12 patients with low amniotic fluid glucose values were delivered of infants within 72 hours as the result of either the presence of infection or the progression of labor. (Am J Obstet Gynecol 1991;164:818-20.)

Key words: Amniotic fluid, glucose, infection

Prematurity is the major cause of perinatal morbidity and mortality. Intrauterine infection is an important causative factor. However, a clear understanding of the role of infection is hampered by traditional tests, which are often insensitive and nonspecific.[1] Clinical signs and symptoms do not correlate well with the gold standard criteria of chorioamnionitis, which are considered to be either a positive amniotic fluid culture or polymorphonuclear leukocytes that extend through the fetal membranes and/or the umbilical cord.[2] Romero et al.[3] demonstrated that Gram's stain examination of amniotic fluid had a sensitivity of 79% and a specificity of 99.6% for the detection of microbial invasion of the amniotic cavity. The Gram's stain is a more rapid assessment for intraamniotic infection than is the conventional amniotic fluid culture. The purpose of this study was to assess the value of amniotic fluid glucose in the diagnosis of intraamniotic infection.

Material and methods

Thirty-nine patients at <34 weeks of gestation with preterm labor and/or premature ruptured membranes were included in the study. Patients were excluded if they had diabetes or had received antibiotics in the past 7 days or if they were in advanced labor with cervical dilatation >4 cm. All patients underwent an

Table I. Glucose concentration

	Glucose concentration (mg/dl)	
Chorioamnionitis	*Amniotic fluid*	*Maternal serum*
Present	5 ± 2.4	89.6 ± 14.06
Absent	39.8 ± 18.42	98.3 ± 30.75
p Value	<0.005	NS

ultrasonography-guided amniocentesis with a 20-gauge spinal needle via an aseptic technique. The amniotic fluid was sent for glucose concentration, Gram's stain, culture, and sensitivity analyses, which included cultures for *Mycoplasma hominis* and *Ureaplasma urealyticum*. Glucose determination was performed by the glucose oxidase method, which is valid at low levels. A concomitant maternal serum glucose value was obtained. Intraamniotic infection was defined as a positive amniotic fluid culture and placental pathologic condition that revealed polymorphonuclear leukocytes that extended through the fetal membranes and/or the umbilical cord. A positive Gram's stain was defined as the presence of bacteria on Gram's stain. The amniotic fluid was not centrifuged. The correlation between intraamniotic infection and amniotic fluid glucose was analyzed. An unpaired Student *t* test was performed for statistical evaluation, and $p < 0.05$ was regarded as significant.

Results

The mean age, gravidity, and parity of patients with intraamniotic infection was 26.1 ± 5.2, 2.7 ± 1.4, and 0.6 ± 0.5, respectively. These values were not significantly different from those of patients without infection, namely, 24.8 ± 6.4, 2.2 ± 1.3, and 0.6 ± 0.9. The mean gestational age of all patients, which was similar in those with intraamniotic infection and in those without infection, was 31.9 ± 4.9 weeks. Nine patients met the criteria for intraamniotic infection, which included both a positive amniotic fluid culture and pathologic findings of the fetal membranes and umbilical cord. Thirty patients studied had no evidence of infection. Those patients with infection had a significantly lower amniotic fluid glucose level, whereas the maternal serum glucose value was not different between the two groups (see Table I). Twelve patients had amniotic fluid glucose values <10 mg/dl. All nine patients with infection had amniotic fluid glucose values <10 mg/dl. The three patients with amniotic fluid glucose values <10 mg/dl in the absence of infection were delivered of infants within 72 hours of admission. All patients with amniotic fluid glucose values <10 mg/dl had either bacteria or white blood cells on Gram's stain or both. Two patients without chorioamnionitis had white blood cells on Gram's stain, as well as amniotic fluid glucose levels >10 mg/dl. Tables II and III further outline the significance of amniotic fluid glucose in the presence of amniotic fluid infection. Six of the nine patients with intraamniotic infection had a positive Gram's stain.

Table II. Chorioamnionitis with amniotic fluid glucose level <10 mg/dl

Positive predictive value	9/9 (100%)
Negative predictive value	27/30 (90%)

	Amniotic fluid glucose	
	<10 mg/dl	*>10 mg/dl*
Chorioamnionitis	9	0
No chorioamnionitis	3*	27

*All of these patients were delivered of infants within 72 hours, despite the absence of chorioamnionitis.

Comment

The incidence of positive amniotic fluid cultures of patients who are in preterm labor varies from 0 to >33%.[4-13] Unfortunately, many of these studies have small numbers of participants. However, positive amniotic fluid culture with chorioamnionitis is one undisputed cause of preterm labor and delivery. A poor correlation between amniotic fluid Gram's stain and culture as found in the current study has been previously reported.[14] False-negative Gram's stains occur with a low organism inoculum ($<10^5$ colony-forming units/ml).[4] Romero et al.[4] failed to increase the sensitivity of the Gram's stain by concentrating the number of organisms with ultracentrifugation of the specimen before the Gram's stain was done. A false-positive Gram's stain may occur when fastidious organisms are seen on the Gram's stain and fail to grow on culturing. Skoll et al.[14] did find a correlation between preterm delivery and a false-negative Gram's stain.

The leukocyte esterase test has been reported to be valuable in the diagnosis of bacterial colonization of amniotic fluid.[15] This rapid, inexpensive test detects neutrophil activity in urine and in other fluids.[16] Hoskins et al.[16a] reported a 91% sensitivity and a 95% specificity of the leukocyte esterase test in the diagnosis of chorioamnionitis. The presence of white blood cells per se in amniotic fluid may[4] or may not[14] be associated with intraamniotic infection. It may be that white blood cell activity as demonstrated by the destructive leukocyte esterase enzyme is the important factor in deter-

mining the presence of intraamniotic infection. Also, the presence of a low intraamniotic fluid glucose level appears to correlate with intraamniotic infection.

Histologic chorioamnionitis has been reported to be associated with amniotrophism that is displayed by polymorphonuclear leukocytes in the extraplacental membranes, placenta, and umbilical cord.[17] The premise on which this is based suggests that diffusible leukotaxic factors are released into the amniotic fluid as part of the inflammatory response.[18] Pankuch et al.[17] found a positive leukotaxic response to be a better predictor of histologic chorioamnionitis than either a positive Gram's stain or an amniotic fluid culture. It is possible that the consumption of amniotic fluid glucose by the leukocytes in response to the amniotrophism could account for the low amniotic fluid glucose levels in this study. Additional study in this regard is required.

This preliminary study indicates that amniotic fluid glucose analysis may be more sensitive and specific than Gram's stain in the diagnosis of intraamniotic infection. The amniotic fluid glucose level was significantly lower in patients with evidence of intraamniotic infection than in patients without infection. Measurement of amniotic fluid glucose is an inexpensive, rapid test that can be performed on amniotic fluid to determine the presence of intraamniotic infection. This test may be considered a helpful addition to Gram's stain, the leukocyte esterase test, and amniotic fluid culture in the identification of intraamniotic infection.

We thank James Martin Wheeler, MD, for statistical help.

Fetal breathing movements after preterm premature rupture of membranes

Alistair B. Roberts, MD, Israel Goldstein, MD, Roberto Romero, MD, and John C. Hobbins, MD

New Haven, Connecticut

Forty-three patients with preterm premature rupture of membranes were studied between 24 and 34 weeks' gestation. Intraamniotic infection was excluded by amniocentesis. There were significantly fewer fetal breathing movements for the first 2 weeks of membrane rupture, compared with controls, with a return to near normal by the third week. This reduction in fetal breathing may play a role in the production of pulmonary hypoplasia in some of these patients. Further studies are needed to investigate whether ruptured membranes are associated with a reduction in fetal breathing at earlier gestational ages. (Am J Obstet Gynecol 1991;164:821-5.)

Key words: Premature rupture of membranes, ultrasound, fetal breathing, pulmonary hypoplasia

Preterm premature rupture of membranes before 24 weeks' gestation is associated with a high perinatal mortality rate.[1] The major causes of death are complications of prematurity, infection, and pulmonary hypoplasia.[2-4] The cause of pulmonary hypoplasia in this setting is still debated, with the two main theories being loss of fetal lung fluid[5] and inhibition of normal fetal breathing.[6]

Fetal breathing movements are considered important for normal lung development. Indeed denervation of the fetal diaphragm in the fetal lamb eliminates fetal breathing movements and impairs lung growth and development.[7, 8] There is conflicting evidence on the role of fetal breathing in the development of pulmonary hypoplasia in human fetuses with preterm premature rupture of membranes. Blott et al.[9] have reported absence of fetal breathing in fetuses that subsequently die of pulmonary hypoplasia. In contrast, Moessinger et al.[10] found no difference in the time spent breathing between fetuses with or without pulmonary hypoplasia.

We have initiated a series of studies to formally address the role of fetal breathing movements in the development of pulmonary hypoplasia. As a first step, we decided to determine the effect of ruptured membranes per se on fetal breathing. Surprisingly there is a paucity of data regarding this important issue. Previous studies in this area have not been able to control for some of the factors known to affect fetal breathing, of which intraamniotic infection is one of the most important.[11] Since amniocentesis is routinely used in this institution in the management of patients with premature rupture of membranes, this afforded the unique opportunity to study fetal breathing in a population where subclinical intraamniotic infection had been reliably excluded.

Material and methods

Patient population. Patients were selected from a data base of 90 patients with preterm premature rupture of membranes occurring before 34 weeks' gestation. A previous publication from this department was based on some cases in this file.[11] It addressed the usefulness of the study of fetal activity in detecting intraamniotic infection. The objective of the study was to determine the effect of ruptured membranes per se on fetal breathing. We therefore excluded patients with conditions known to affect fetal breathing.[12]

Inclusion criteria. Patients were included if they met the following criteria: (1) gestational age of 24 to 34 weeks with a singleton pregnancy; (2) no maternal disease or drug usage; (3) clinical and laboratory documentation of premature rupture of membranes (ferning, Nitrazine test, and pooling of fluid); (4) no contractions, evidence of labor, or delivery within 24 hours of the examination; (5) amniocentesis to exclude intraamniotic microbial invasion of the amniotic cavity; and (6) a neonatal birth weight above the tenth percentile for gestational age.[13]

Amniotic fluid microbiologic composition. Amniotic fluid was cultured for aerobic and anaerobic bacteria, *Mycoplasma hominis*, and *Ureaplasma urealyticum* by

methods previously described.[11] Patients with positive cultures for any of these microorganisms were excluded from this study. Amniocentesis was standard clinical management in the department. An amniocentesis was performed within 24 hours of admission, if possible, or after bed rest to try to prevent amniotic fluid drainage so as to permit amniocentesis. The amniocentesis was repeated weekly or more frequently if infection was clinically suspected.

Fetal activity recordings. Fetal breathing and fetal trunk movements were studied with real-time ultrasonography. Studies were performed 30 to 120 minutes after breakfast. All patients were on a normal diet. Ultrasonographic recordings were of 30 minutes' duration. These were videotaped, and the amount of breathing and trunk movements was measured with a stopwatch. All breathing movements were recorded, except for isolated single breaths. The beginning and end of each breathing session were timed with a stopwatch, and the total amount of time the fetus spent breathing in each session was expressed as a percentage. Trunk movement was recorded in the same manner with a stopwatch used to record the beginning and end of each trunk movement. Tapes were analyzed the same day with no knowledge of the amniocentesis results.

Recordings used in this study were those made within 24 hours of an amniocentesis; a total of 64 recordings were obtained in 43 patients. Seventy-one percent of the recordings were made before amniocentesis.

Study design. To determine the effect of ruptured membranes on fetal activity, it was necessary to allow for changes caused by gestational age. We therefore divided the patients into three groups: (1) 24 to 27 weeks, (2) 28 to 31 weeks, (3) 32 to 34 weeks. Normal fetuses from women with matched gestational ages and intact membranes were used as controls.[14] Only one recording per patient (that obtained during the first week) was selected for each gestational age interval.

Two approaches were used to describe changes in fetal activity over time: a longitudinal and a cross-sectional approach. Eight patients had serial recordings over 3 weeks within the interval of 28 to 34 weeks. They provided the data for longitudinal observations.

For the cross-sectional study patients were divided into three groups according to the duration of ruptured of membranes (1 week, 2 weeks, and 3 weeks). One recording per patient per week interval was used. The control group consisted of normal women with intact membranes between 28 and 34 weeks' gestation.

Statistical analysis. For all cross-sectional comparisons only one recording per patient was used. Comparisons were made between the study group (rupture of membranes) and the control group (intact membranes). A Wilcoxon rank sum test was used to analyze fetal activity as the data were not normally distributed. Longitudinal observations were analyzed with a randomization test for matched samples.[15] Calculations were performed with the True Epistat program (Epistat Services, Richardson, Tex.).

Results

Fetuses with ruptured membranes spent significantly less time breathing than those with intact membranes (mean, 14.3%; median, 9.4%; range, 0 to 93% vs mean, 33%; median, 27%; range, 0 to 90%; respectively; $p < 0.001$). The amount of time spent breathing was significantly reduced at all gestational ages from 24 to 34 weeks as illustrated in Table I.

The results of the longitudinal study are displayed in Fig. 1 and Table II. The amount of time spent breathing increased with the duration of rupture of membranes ($p = 0.06$). In contrast, no change occurred in trunk movement over time. These observations were confirmed by cross-sectional analysis (Table III). The amount of time spent breathing was significantly less in the first 2 weeks of membrane rupture

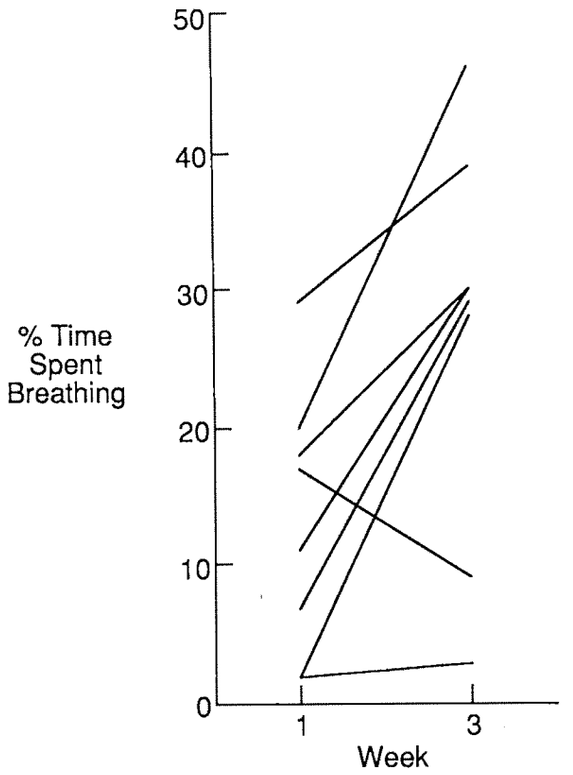

Fig. 1. Percentage of time spent breathing at 1 week and 3 weeks of membrane rupture in eight fetuses in longitudinal study.

compared with the control group ($p < 0.001$ and $p < 0.01$, respectively). In contrast, no difference was observed in time spent breathing between the group in the third week of membrane rupture and the control group. Of considerable interest is that the total duration of fetal trunk movement was not different from the control at any interval.

No significant difference was found between the amounts of fetal breathing or fetal movement in recordings made before and after amniocentesis.

Comment

Our data clearly indicate that rupture of membranes was associated with a significant reduction in the amount of time the fetus spent breathing. This effect was dramatic and occurred at all gestational ages examined from 24 to 34 weeks' gestation. The reduction in breathing lasted for at least 2 weeks and then returned to normal values. In the majority of cases this was not accompanied by a similar reduction in fetal trunk movements.

Why should rupture of membranes be associated with a significant reduction in fetal breathing activity? Since the phenomenon is not associated with decreased fetal trunk activity, rupture of membranes does not seem to produce a generalized depression in fetal motor activity. Several mechanisms could be invoked to explain our findings, including infection, labor, and hypoxia. Subclinical microbial invasion of the amniotic cavity has been associated with a significant reduction in fetal breathing activity in the setting of preterm premature rupture of membranes.[11] This possibility has been excluded as all patients had a negative amniotic fluid culture for bacteria and mycoplasma species around the time of study. None of our patients were in labor or were delivered within 24 hours of the study. Hypoxia was unlikely to play a major role, because these fetuses did not have any evidence of fetal distress, fetal trunk movements were not affected, and there was no evidence of growth retardation. Amniocentesis has been reported to reduce fetal breathing activity for 48 hours.[17] No evidence could be found in this study that amniocentesis in patients with premature rupture of

membranes further reduced fetal breathing activity. In the majority of recordings the amniocentesis was performed after the recording of fetal activity.

These findings have clinical and physiologic implications. Fetal breathing and fetal movements are part of the biophysical profile that has been advocated for the diagnosis of infection in patients with preterm premature rupture of membranes. Whereas the presence of fetal breathing has a high negative predictive value for intraamniotic infection, a depression in fetal breathing activity is nonspecific. Our data indicate that preterm premature rupture of membranes in the absence of infection is associated with a significant and prolonged reduction in fetal breathing. Fetal trunk movement is significantly reduced in the presence of intraamniotic infection but not in rupture of membranes per se and therefore may be more useful in diagnosing infection in fetuses with depressed fetal breathing activity. The vast majority of fetuses with intraamniotic infection will have reduction in both breathing and trunk movements, and we have shown that the measurement of such parameters is useful clinically.[11]

The physiologic implications of a 2-week reduction in fetal breathing revolve around the subject of lung growth. There are conflicting reports about the role of fetal breathing in pulmonary hypoplasia. Studies by Blott et al.[9, 18] noted that fetuses with premature rupture of membranes and pulmonary hypoplasia had reduced amounts of fetal breathing. However, interpretation of these findings is difficult because of the definition of "breathing" used in the study and because the mean gestational age at delivery was 26 weeks. Breathing was considered to be present if thoracic movements were present for a continuous period of 60 seconds in a recording session of 30 to 120 minutes. We are unaware of data indicating what proportion of normal fetuses breathe for 60 seconds continuously before 24 weeks' gestation. One study has indicated that only 59% of normal fetuses have 60 seconds of continuous breathing in a 30-minute recording between 25 and 28 weeks' gestation.[19] In contrast, Moessinger et al.[10] studied 10 patients with prolonged ruptured membranes from 25 to 35 weeks' gestation and found no difference in time spent breathing between fetuses with and without pulmonary hypoplasia. This study used a 60-minute recording period and measured the percentage of time spent breathing. Breathing was defined as starting when there was a breath followed by two others or more within a 6-second window. Interestingly, in the cases without pulmonary hypoplasia the percentage of time spent breathing was significantly less than that of controls between 30 and 35 weeks' gestation.

Animal studies have suggested that both loss of lung fluid and inhibition of fetal breathing can lead to pulmonary hypoplasia and that the effects are additive.[5] Studies in the guinea pig also suggest that even short periods of oligohydramnios can interfere with lung growth.[20] It is possible therefore that a 2-week reduction of fetal breathing in the human fetus at a critical period in lung growth and development might lead to pulmonary hypoplasia. Thibeault et al.[21] concluded that pulmonary hypoplasia in the human fetus could develop after only 6 days of membrane rupture.

This study investigated the effect of prolonged rupture of the membranes on fetal breathing at 24 to 34 weeks' gestation. However, the critical period in human fetal lung growth is before 24 weeks' gestation. Further studies are needed to investigate whether there is inhibition of breathing at earlier stages of gestation. There is also a need for more information on normal patterns of fetal breathing before 24 weeks.

Outpatient sedation: An essential addition to gynecologic care for persons with mental retardation

David A. Rosen, MD,[a] Kathleen R. Rosen, MD,[a] Thomas E. Elkins, MD,[b] H. Frank Andersen, MD,[b] S. Gene McNeeley, Jr., MD,[b] and Cheryl Sorg, RN[b]
Ann Arbor, Michigan

Routine gynecologic care for persons with mental retardation may be difficult to provide, especially to those women who do not allow a pelvic examination to be performed. Of 275 women referred to a multidisciplinary clinic addressing the reproductive health concerns of mentally retarded women, 61 patients (22%) did not allow a gynecologic examination to be performed. The administration of ketamine alone, midazolam alone, or a combination of midazolam and ketamine allowed for the successful performance of a gynecologic examination in 81% of previously uncooperative women. No adverse effects of the medications were noted. We conclude that sedation of difficult-to-examine, mentally handicapped women can be safely performed in the outpatient setting, thus avoiding the need for general anesthesia and its inherent risks. (Am J Obstet Gynecol 1991;164:825-8.)

Key words: Mental handicap, sedation, ketamine, midazolam, oral sedation

Routine outpatient gynecologic care for persons with mental retardation, including a pelvic examination, is legally mandated by most states but has been difficult to provide in many settings and has been relatively unobtainable for many patients. The lack of cooperation during attempted pelvic examinations, concerns about the use of physical force or excessive coercion, and the incompleteness of pelvic examinations in uncooperative patients have been identified by primary care providers as the leading reasons for the avoidance of the outpatient evaluation of women with mental retardation.[1] This reluctance by the primary care provider to perform pelvic examinations in this population has resulted in >40% of initial visits to the gynecology clinic at the University of Michigan for persons with mental retardation being scheduled as the person's first pelvic examination.[2] In an effort to enhance the availability of routine gynecologic care for persons with mental retardation, a program for outpatient sedation was begun. The sedation program briefly mentioned in prior publications is fully described in this report.[3]

Only a few isolated case reports exist concerning the sedation of persons with mental retardation in any age group.[4,5] Guidelines have been established for the practice of sedation in the medical specialties of pediatrics, dentistry, and radiology.[6,7] However, these documents do not evaluate the safety or efficacy of individual sedative regimens.

The purpose of this study was to evaluate the safety and efficacy of oral ketamine and/or midazolam for the sedation of the difficult-to-manage patient with mental retardation in an outpatient gynecologic setting.

Sedation scale					
1	*2*	*3*	*4*	*5*	*6*
Normal	Calm but with full muscle tone	Drowsy with mild muscle relaxation	Drowsy with physically relaxed muscle tone	Eyes closed; responds to minor stimulation; airway reflexes intact	Asleep; does not respond to stimulation; airway reflexes absent

Methods

This study received institutional approval by the human use and ethics committees. Mentally handicapped women in whom previous attempts at performing a gynecologic examination had been unsuccessful were entered into this study as an alternative to examination while they were under general anesthesia. Examination and the sedation were performed in the outpatient gynecology clinic. Patients received nothing by mouth for 6 hours before the clinic appointment. (This is easily monitored in the highly supervised and activity-structured living environments of the patients in this study.) An anesthesiologist was present to administer the medications and monitor the patients who remained under continuous medical observation during the study period. Heart rate, blood pressure, respiratory rate, and level of sedation were measured every 15 minutes. Sedation was evaluated before the examination and measured with a six-point scale (see Table I). No change in mental status as compared with baseline was recorded as a score of 1. A patient with eyes closed received a score of 5, whereas a deeply sedated patient would receive a score of 6. Oxygen, suction, and airway and resuscitation equipment was available. A primary directive of the clinic was to be as nonthreatening as possible; therefore no sedative medications were given by parenteral routes.

The initial dose of all medications was administered by the oral route. Subsequent medications were given intranasally if this route was acceptable to the patient or orally if the patient refused intranasal medication. Three regimens were studied: ketamine alone, 4 to 10 mg/kg; midazolam alone, 0.1 to 0.4 mg/kg; and ketamine, 4 mg/kg plus midazolam 0.4 mg/kg. Unflavored liquid preparations of these drugs were mixed with either flavor extracts or chocolate syrup to facilitate acceptance of oral medication. Intranasal medications were not diluted. Adequacy of sedation was assessed every 15 minutes. Gynecologic examination was attempted when a sedation score ≥ 3 was achieved. If the sedation score was still <3 at 45 minutes, an additional sedative dose was given. The occurrence of any adverse side effects from the sedatives was noted. Patients were discharged from the clinic when they had resumed their usual level of functioning.

The following additional patient demographic data were recorded: patient's age and weight, medication and allergy history, prior visits to the sedation clinic, time until return to normal function, and level of cognitive function. The patient's functional status was gauged on a five-point scale. A score of 1 indicated minimal impairment, whereas a score of 5 indicated a severe handicapping condition (see Table II).

The majority of the patients (60%) were very severely impaired (score = 5). Twenty percent of the women were less severely handicapped (score = 4), whereas patients with moderate handicap (score = 3) made up the remaining 20% of the population.

Results

During the 18-month study period, 275 patients were referred to the model clinic for gynecologic consultation. Sixty-one patients (22%) were scheduled for a total of 102 examinations with the sedation protocol, and 52 of these 61 patients (81%) were successfully examined. A total of 85 of these 102 visits resulted in successful examinations.

Gynecologic examination was possible after only one dose in 47 patient visits, 25 patients requiring a second dose were successfully examined, and only 13 patients required a third sedative dose before examination was possible. The initial regimen selected was ketamine in 60%, midazolam in 34%, and a combination in 6%. There was no significant difference in the occurrence of adequate sedation as a function of the initial medication selection. If a second dose was required, midazolam alone was chosen in two thirds of cases regardless of the initial medication. All patients with moderate mental handicap were successfully examined. The mean ketamine dose was 8.0 mg/kg. The mean dose for those patients who received midazolam as the primary agent was 0.46 mg/kg, whereas those who received the combination of midozalam and ketamine had a mean dose of 0.34 mg/kg. Although the means differed slightly for those who received midazolam, this difference was not statistically significant.

A successful gynecologic examination was considered to be one in which a bimanual examination was allowed for the adequate palpation of pelvic organs or one that excluded significant pelvic abnormalities. A speculum

Table II. Parameters of mental function scale

Mental function scale				
1	*2*	*3*	*4*	*5*
Upper-moderate motor and/or mental disability	Moderately mentally handicapped	Severely mentally handicapped	Severely mentally handicapped with some physical disability	Profoundly mentally handicapped with some associated physical disability

examination was successfully performed in only 52%. However, Papanicolaou smears were obtained from 87% of women during speculum examinations or by guiding the cotton swab into the cervical os with one finger in the vagina. Examinations were initially attempted when the patient reached a level of 3 on the sedation score. The maximum sedation score received by any of the patients was 5. This occurred in 16% of patient visits.

All patients with moderate mental handicap were examined. In patients with more than moderate mental handicap, failure to complete an examination occurred for two reasons: (1) One patient was well sedated, but increased muscle tone impeded the examination during three consecutive clinic visits. This patient returned to the sedation clinic on one occasion after the examination while she was under general anesthesia and refused all sedation medication. (2) Some patients refused a repeat medication dose. Eight patients refused supplemental oral or nasal medication during 13 clinic visits.

In the nine patients who could not be examined, the failure to perform an examination resulted in a total of eight examinations with patients under general anesthesia. Three of these examinations were in the same patient, who was undergoing follow-up of an underlying gynecologic condition. In three of the patients with "failure," the need for more complete examinations at the time was outweighed by the risks of general anesthesia.

A significant change in blood pressure, heart rate, or respiratory rate was not demonstrated in any patients. None of the patients received any parenteral sedative medications. Patients had no difficulties in supporting their own airways, and there was no need to secure intravenous access in any patient. Conjunctival erythema was observed when sedation was achieved and dissipated as the patient returned to normal functioning. Nausea with or without vomiting was the most frequent side effect observed. The incidence of nausea decreased from 38% to 21% when the oral medications were mixed in chocolate syrup rather than flavor extract. Of those who did vomit, only 35% had more than one episode. Vomiting usually occurred before examination (before a sedation level of 3 was obtained). No patient manifested any agitation or signs of dysphoria or experienced an increase in oropharyngeal secretions. No airway obstruction occurred. Prolonged lethargy (sedation score ≥3) for 12 hours after the procedure was noted on three occasions. The median time from examination to discharge from the clinic was 45 minutes. Eighty percent of patients were discharged after 1 hour, 16% after 90 minutes, and the remainder by 2 hours.

Comment

This manuscript reports the development and evaluation of a sedative regimen for use in the mentally handicapped patient undergoing a gynecologic examination. The goal of this regimen was to provide safe, reliable, short-term sedation for use in an outpatient setting without using a parental route of administration. There is limited information available about either the nasal or oral route of administration for ketamine and/or midazolam in the normal adult population.[8, 9] However, these agents are routinely administered by these routes as preoperative sedatives in pediatric and adolescent patients, where excellent results have been achieved.[10] Our study demonstrates that similar results can be achieved with orally and nasally administered ketamine and midazolam in patients with mental retardation.

Grant et al.[8] describe the pharmacokinetics after a single oral administration of ketamine 0.5 mg/kg. Peak plasma concentrations occurred at 45 minutes and none of the patients lost consciousness. Ketamine was chosen because of its short duration of action and its capacity to maintain hemodynamic stability. In non–mentally handicapped patients, low-dose ketamine (0.5 mg/kg) allows maintenance of airway reflexes and also produces minimal respiratory depression. This study has demonstrated that in patients with mental retardation an elevated dose (8 mg/kg) has proved effective and offers the same advantages mentioned previously.

Dysphoric reactions have been noted when the drug is given parenterally to adults, but adverse effects after an oral sedative dose of ketamine have not been reported in normal adults.[8] Hollister and Burn[11] noted that the incidence of unpleasant dreams and hallucinations is higher in older children and adults than in

younger ones. It may be that this dysphoric reaction requires higher levels of cognition. This may explain why children and perhaps some persons with mental retardation have a lower incidence of dysphoric reaction to ketamine than do adults. The mentally retarded patients in this study required a mean total oral ketamine dose of 8 mg/kg to produce effective sedation, and peak effect was noted to occur at 45 minutes after administration.

Midazolam was chosen because it is a rapid-acting agent with a short duration of action. The oral administration of midazolam to adults has been investigated by Heizmann et al.[9] Absorption appears to occur rapidly with peak plasma levels reached within 30 minutes; however, bioavailability is quite variable (from 31% to 72%) because of the high liver extraction.[9] It has been effectively used via nonparenteral routes for preoperative sedation in children.[10]

At this time the major drawback of this regimen is that oral preparations for ketamine or midazolam are currently unavailable in this country. The parenteral solutions are quite bitter and unpalatable. In this study the vehicle (a flavored [cherry, grape, etc.] alcohol-containing extract) that was initially used to deliver the drugs produced an undesirably high incidence of nausea and/or vomiting. The occurrence of nausea decreased from 38% to 21% when the drugs were delivered in chocolate syrup; however, the proportion of patients who refused medication remained quite high (18%).

Ketamine and midazolam both have been used effectively for sedation by both oral and intranasal routes. The advantage of the intranasal route was a more rapid onset of effect (5 minutes for nasal, 30 minutes for oral). Only three of the patients would accept the nasal medications before receiving the oral medication. The rest required some sedative effect from the oral medication before they would allow nasal administration. Although there was interaction between midazolam and ketamine as demonstrated by the results, their effects did not appear to be simply additive. Ketamine appeared to be more effective in the severely handicapped patient, whereas midazolam was easier to titrate to appropriate levels of sedation in the less handicapped individual. As it may be difficult to predict when a patient will allow a pelvic examination, examination should be attempted when a level of 3 is reached. This will avoid the need for additional medication doses.

We were unable to successfully examine 9 of 61 patients. One of these patients could not be examined during four consecutive appointments. Three patients refused to accept the medication during one or more clinic visits. Five of the patients who would not tolerate the initial gynecologic examination were successfully sedated and examined during a subsequent clinic visit. Despite these sedation failures, the program is considered to be a success for all involved.

A sedation program such as we have described offers significant cost savings to the public. The average total hospital and physician charge for an examination under anesthesia is approximately $2000 at the University of Michigan Medical Center; in this series the approximate cost of each outpatient gynecologic examination that was performed with oral-nasal sedation was $60 to $80. Thus savings for the public were more than $100,000 and these handicapped women avoided the risks associated with general anesthesia.[12]

In summary, the above-described sedation program has greatly enhanced the ability of the gynecology service to provide humane, cost-effective care to previously unmanageable patients. However, we caution against the indiscriminate administration of these sedative agents.

Does unexplained second-trimester (15 to 20 weeks' gestation) maternal serum α-fetoprotein elevation presage adverse perinatal outcome?

Pitfalls and preliminary studies with late second- and third-trimester maternal serum α-fetoprotein

Joe Leigh Simpson, MD, Sherman Elias, MD, Cynthia D. Morgan, RN, MS, Richard N. Andersen, PhD, Lee P. Shulman, MD, Baha M. Sibai, MD, and Amanda Skoll, MD

Memphis, Tennessee

Several reports have suggested that persons with an unexplained maternal serum α-fetoprotein elevation at 15 to 20 weeks' gestation are at an increased risk for a variety of other pregnancy complications (e.g., preeclampsia) and adverse perinatal outcomes (e.g., fetal death, low-birth-weight infants). However, ascertainment biases could explain some of these reported findings, and predictive value of unexplained elevated maternal serum α-fetoprotein levels in the prediction of pregnancy complications seems limited. If elevated second-trimester levels were truly predictive of pregnancy complications, we reason that third-trimester levels could prove even more useful. We thus studied late second-trimester and early third-trimester (24 to 36 weeks' gestation) maternal serum α-fetoprotein levels with the same enzyme immunoassay we use to evaluate routine second-trimester (15 to 20 weeks' gestation) levels. Values rose up to 32 weeks and fell slightly thereafter. Variance was greater than at 15 to 20 weeks but not so great as to preclude clinical usefulness in the third trimester. Of 279 women with a normal (0.4 to 2.49 multiples of the median) maternal serum α-fetoprotein value at 15 to 20 weeks' gestation, 270 (96.8%) showed levels in the same range later in gestation; however, none of six singleton pregnancies with unexplained maternal serum α-fetoprotein levels > 2.50 multiples of the median at 15 to 20 weeks' gestation showed maternal serum α-fetoprotein levels in this range at 24 to 36 weeks' gestation. The relationship between second- and third-trimester maternal serum α-fetoprotein levels in abnormal pregnancies remains to be elucidated in a large sample. Thus we are conducting not only cohort but also cross-sectional studies. Preliminary findings suggest that women with preterm premature rupture of membranes or with premature labor show elevated late second-trimester and early third-trimester maternal serum α-fetoprotein levels; however, larger sample sizes are necessary. (Am J Obstet Gynecol 1991;164:829-36.)

Key words: Third trimester, maternal serum α-fetoprotein, pregnancy complications, adverse outcome

Second-trimester maternal serum α-fetoprotein (AFP) screening for the detection of neural tube defects is accepted obstetric practice. However, relatively few maternal serum AFP elevations are actually associated with fetal neural tube defects. Erroneous gestational age assignment, multiple gestation, and fetal death are common explanations, and a host of rare explanations (e.g., congenital nephrosis) have been reported. However, there remain many pregnancies in which there is no ostensible explanation for elevated maternal serum AFP levels. The significance of unexplained elevations is uncertain, but several reports suggest that such persons are at an increased risk not only of pregnancy loss but of a variety of other pregnancy complications (e.g., preeclampsia) and adverse perinatal outcomes (e.g., low-birth-weight infants).[1-7] In fact, a committee of the American Society of Human Genetics stated that "women who have increased concentrations of MSAFP and whose fetus does not have a demonstrable abnormality by either level II ultrasound or karyotyping from amniotic fluid continue to have an increased risk for

having a fetus with major congenital malformation and poor pregnancy outcomes, such as perinatal death and low birthweight."[8]

Although not unaware of the potential utility of maternal serum AFP in the identification of women at increased risk of pregnancy complications, we are concerned that incorporation of the above recommendation into obstetric practice is premature.[9] Not only could ascertainment biases be responsible for some of the reported findings (see Comment), but sensitivity and specificity for use of unexplained elevated maternal serum AFP levels as a predictor of pregnancy complications are limited. Moreover, it remains to be determined whether those women with unexplained maternal serum AFP elevations who later manifest pregnancy complications are distinct from those already known clinically to be at increased risk on the basis of history (e.g., hypertension, vaginal bleeding, fetal growth discordant for dates). Such a characteristic would obviously need to apply before recommending routine (15 to 20 weeks' gestation) second-trimester maternal serum AFP examination for identification of pregnancy complications, yet this point appears not to have been raised in previous publications.

How can the obstetric significance of unexplained second-trimester maternal serum AFP best be determined? If elevated second-trimester maternal serum AFP levels were truly predictive of pregnancy complications, we reason that third-trimester maternal serum AFP levels could prove even more useful. All antepartum tests have a finite time for the prediction of poor outcome, and the maternal serum AFP test should be no exception. If a given test has value in the identification of pregnancy complications or adverse perinatal outcome, the predictive value should be higher near the time such complications are usually manifested. In fact, failure to find a relationship between elevated third-trimester maternal serum AFP and adverse perinatal outcome might cast doubt on claims of a relationship between unexplained elevated second-trimester maternal serum AFP levels and subsequent adverse perinatal outcome. In this article we shall first discuss the significance of unexplained elevated levels in the second trimester (15 to 20 weeks' gestation) and then present our preliminary findings concerning late second-trimester and early third-trimester (24 to 36 weeks' gestation) maternal serum AFP levels.

Methods and preliminary results

Assay for late second-trimester and early third-trimester maternal serum AFP levels. In our laboratory, the Abbott enzyme immunoassay is used for routine measurement of second-trimester maternal serum AFP. The average interassay coefficient of variation at 15.9 ng/ml is 6.5%; at 83.7 ng/ml, 7.3%; and at 219 ng/ml, 8.1%. This assay was used without modifications for this study of late second-trimester and early third-trimester maternal serum AFP.

Blood samples were obtained from unselected women receiving obstetric care at the Regional Medical Center (Thomas F. Gailor Clinics). In this large urban hospital (7800 deliveries per year), 80% of patients are black; 20% are white. Their socioeconomic status is predominantly low income to lower middle class. The proportion with obstetric complications is relatively high (e.g., 11% preeclampsia). Samples in this study were stored at −70° C until collection was completed and assays were performed in batches.

The interval of 24 to 36 weeks' gestation was chosen for the generation of late second-trimester and early third-trimester standards. Obstetric interventions would probably need to occur during this interval to affect pregnancy outcome favorably. Fig. 1, *A* and *B*, shows maternal serum AFP values that are not weight adjusted. Although weight adjustment is routine in second trimester, it is not clear whether adjustments used at 15 to 20 weeks' gestation would be appropriate later in gestation (24 to 36 weeks). Applying second-trimester weight adjustments did not substantively alter results; however, lack of certainty concerning validity of an extrapolated weight adjustment leads us to display raw data (Fig. 1). After pregnancies were completed, medical records were reviewed to identify subjects whose gestational age had been assigned incorrectly when the blood sample was obtained. In 43 subjects original dating appeared erroneous because the dating differed by >2 weeks from that based on the agreement of ultrasonographic examination later in pregnancy, delivery date, and birth weight. That is, the latter three were in agreement and contradictory to our original assignment. Fig. 1, *B*, shows maternal serum AFP values by gestational week before and after adjustment. No significant change in medians occurred as a result of this reassignment. That so few gestational ages were in error probably reflects our relatively frequent use of ultrasonography early in pregnancy. Nonetheless, in this article we use values based on uncorrected gestational age because such an approach is conventionally used to generate maternal serum AFP medians.

Fig. 1 demonstrates that maternal serum AFP level rises between 24 and 32 weeks' gestation, although not so rapidly as earlier in pregnancy. We observed rising maternal serum AFP levels until 32 weeks' gestation, consistent with two previous studies,[10, 11] but not with another study that shows a plateau early in the third trimester (28 weeks' gestation).[12] Although maternal serum AFP levels are obviously more variable in the third trimeser than in the second trimester, third-trimester variance seems not so large as originally reported.[10, 11] (SD rather than standard error is the appropriate mea-

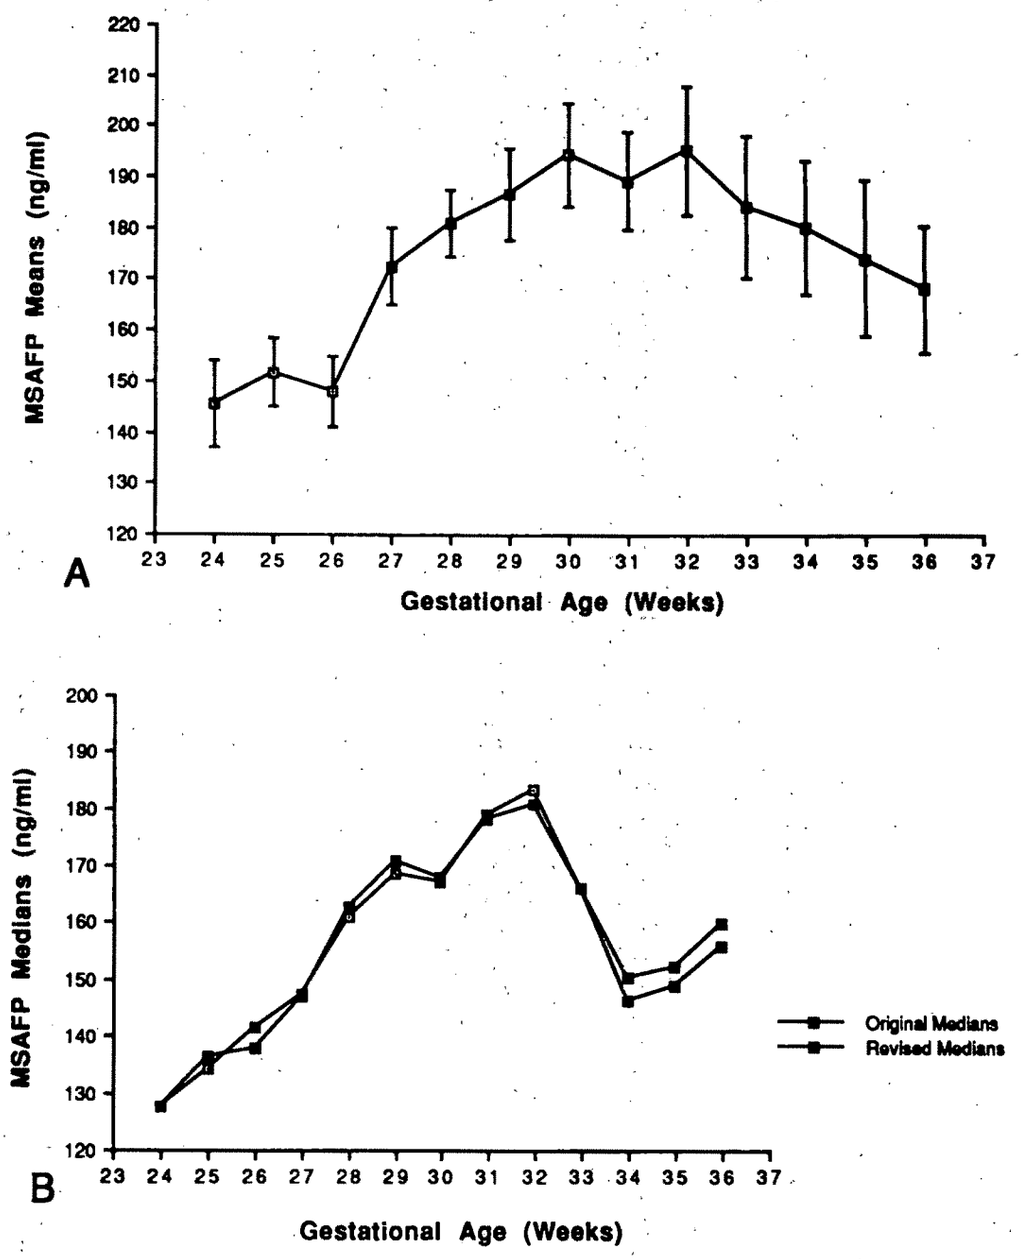

Fig. 1. Maternal serum AFP (MSAFP) values between 24 to 36 weeks' gestation. **A,** Means (±SE). **B,** Medians with and without gestational age correction.

sure because maternal serum AFP values are not normally distributed.) Second-trimester (15 to 20 weeks' gestation) SDs on a comparable number of samples in our laboratory were approximately 30 to 40 ng/ml, compared with 60 to 70 ng/ml for the late second-trimester and early third-trimester (24 to 36 weeks' gestation). We concluded that the magnitude of the variance was not so great as to preclude maternal serum AFP being clinically useful in the third trimester.

Correlation between maternal serum AFP in second and third trimester. Encouraged by the ability to assay maternal serum AFP reproducibly at 24 to 36 weeks' gestation, we next sought to determine the correlation among levels at various stages of gestation with samples obtained in the process of generating the above data.

In 354 women a single maternal serum AFP value at 15 to 20 weeks' gestation and a single value at 24 to 36 weeks' gestation were available (Table I). Most (270 of 279 or 96.8%) women with a normal (0.4 to 2.49 multiples of the median) second-trimester value showed

maternal serum AFP in a similar range (0.4 to 2.4 multiples of the median) later in gestation (24 to 36 weeks). This is explored further in Fig. 2, which shows serial values in 15 women with three or more values. On the other hand, none of six women with singleton pregnancies and unexplained second-trimester maternal serum AFP elevations (>2.50 multiples of the median) showed late second-trimester and early third-trimester values in this range, even though two of the six actually had an adverse perinatal outcome (Table II). Of the 24 subjects studied in the original investigation who had a late gestation maternal serum AFP level > 2.5 multiples of the median, values had been obtained in the late second-trimester or early third-trimester in nine; all nine showed levels between 0.40 and 2.49 multiples of the median. Two of the 24 experienced a fetal death and several others had abnormal outcomes (Table III). The possibility that both routine second-trimester (15 to 20 weeks) and late second-trimester and early third-trimester (24 to 36 weeks) maternal serum AFP levels have independent positive predictive value needs to be explored.

Comment

Unexplained second-trimester maternal serum AFP elevations. In the 1977 United Kingdom Collaborative Study, Wald et al.[1] reported the mean birth weight to be 281 gm lower in pregnancies associated with unexplained elevated (>2.0 multiples of the median) maternal serum AFP levels than in pregnancies associated with normal second-trimester levels. Levels > 2.0 multiples of the median were observed in 15.8% of stillbirths, 14.8% of neonatal deaths, and 16.3% of low-birth weight (<1500 gm) infants. Only 5.8% of normal singleton pregnancies showed maternal serum AFP levels > 2.0 multiples of the median. In North Carolina, Burton et al.[5,6] reported that patients with unexplained elevations (>2.5 multiples of the median) exhibited a significantly increased frequency of pregnancy complications. The frequency of fetal losses after 20 weeks' gestation was 4.0% in women with unexplained maternal serum AFP elevations, as compared with 0.5% in those with no elevation. Increases were observed for birth weight < 2500 gm (15% vs. 7.2%), neonatal deaths (2.1% vs. 0.5%), and nonchromosomal congenital anomalies (6.2% vs. 1.4%). Similar claims concerning birth weight and other adverse outcomes have been made by others.[2,3,4]

Nelson et al.[7] studied 166 patients with unusually

*No formula for weight adjusting late second-trimester and early third-trimester values. Applying the routine second-trimester formula to such values would have resulted in maternal serum AFP of subject 5 still being ≥2.5 multiples of the median and all other subjects <2.5 multiples of the median.

high maternal serum AFP levels (>5 multiples of the median). Of these, 100 (66%) had a subsequent pregnancy complication. The complication rate was 30% if levels were 4 to 4.9 multiples of the median, 26% if levels were 3 to 3.9 multiples of the median, and 14% if levels were 2.5 to 2.9 multiples of the median. A correlation between frequency of complications and degree of maternal serum AFP elevation was partially confirmed by Robinson et al.[13] From an initial sample of 35,787 women, 560 with unexplained maternal serum AFP > 2.5 multiples of the median were identified. The frequency of stillbirths increased as maternal serum AFP levels increased, although this did not hold for intrauterine growth retardation.

With respect to pregnancy complications other than fetal death or growth retardation, Clayton-Hopkins et al.[14] reported that maternal serum AFP values were elevated in pregnancies complicated by hypertension. This finding was also observed by Mizejewski and Risemberg.[15] In a case-control study by Milunsky et al.[16] women whose pregnancies were characterized by obstetric complications were matched with women whose pregnancies had normal outcomes. Increased odds ratios were observed between elevated second-trimester maternal serum AFP levels and the following adverse perinatal outcomes and pregnancy complications: fetal death (8.1), low birth weight (4.0), newborn complications (3.6), oligohydramnios (3.4), abruptio placentae (3.0), preeclampsia (2.3), premature rupture of membranes (2.0), and polyhydramnios (1.6). It is noteworthy that these complications are not independent of each other. Moreover, corrections for multiple comparisons were apparently not made.

Although intriguing, objections can be raised to the experimental designs of some of the above studies. Biases of ascertainment probably exist in some studies. One obvious pitfall would arise if blood samples were preferentially submitted from women already suspected of having a complication (ascertainment bias). This pitfall was especially likely to have been a problem before examination of maternal serum AFP became routine (circa 1985). If some fetuses were moribund, if in fact not already dead, maternal serum AFP levels might merely be secondarily elevated. Misclassification of an inviable pregnancy as viable would contribute to an apparent association between maternal serum AFP elevation and fetal death and possibly other complications. If the purported association were applied clinically to women known to have viable pregnancies at the time of screening, risks would be overestimated. Burton et al.[2, 3, 7] verified fetal viability at the time of maternal serum AFP screening. The assumption of fetal viability is also plausible in the case-control study of Milunsky et al.,[16] because this study was conducted relatively recently, at a time of high use of ultrasonography. However, viability at the time of sampling cannot be assumed in all studies. One could also envision circumstances in which unexplained second-trimester maternal serum AFP elevations would carry no significance for untoward outcome because the pathogenesis for the elevation would be transient. For example, maternal-fetal hemorrhage could lead to a rise in maternal serum AFP level. If no further bleeding occurred, perinatal outcome would not necessarily be unfavorable. Another circumstance in which transient maternal serum AFP elevation is not necessarily associated with adverse clinical consequence is that in which resorption of a dead co-twin occurs.

Finally, it is uncertain whether unexplained maternal serum AFP elevation is predictive of complications in

*No formula for weight adjusting late second-trimester and early third-trimester values. Application of the routine second-trimester formula to these values would have resulted in maternal serum AFP of subjects 7, 10, and 17 falling to <2.5 multiples of the median.

women not otherwise suspected of having obstetric problems. Perhaps unexplained elevation merely confirms pregnancies already recognized clinically to be at increased risk as a result of pregnancy complications such as preeclampsia, preexisting maternal illnesses (e.g., diabetes mellitus), bleeding, or complications in a previous pregnancy. If so, unexplained maternal serum AFP elevation would add little to what the alert obstetrician already knows. Clearly data are needed that state the predictive value of elevated maternal serum AFP levels in women manifesting no known risk factors who are known to have a viable pregnancy.

In conclusion, data seem insufficient to justify aggressive surveillance in pregnancies of otherwise nor-

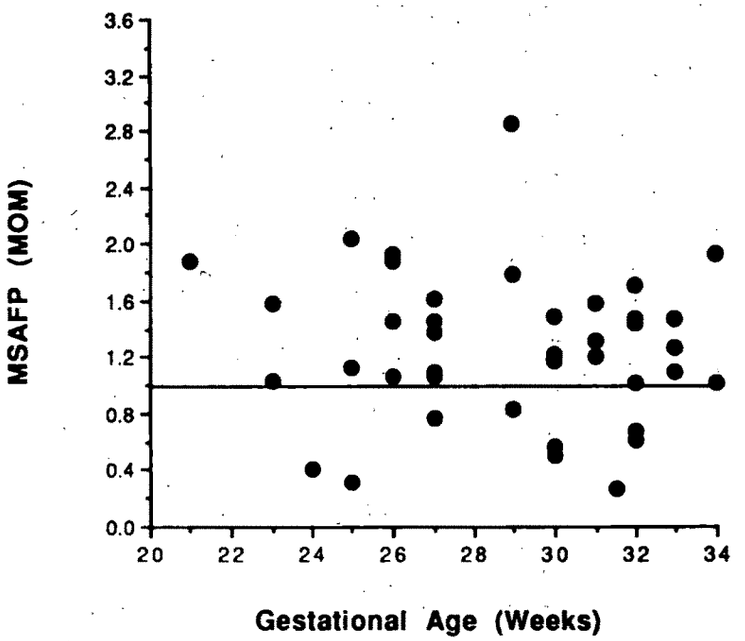

Fig. 3. Maternal serum AFP (MSAFP) in women with premature rupture of membranes not yet in labor.

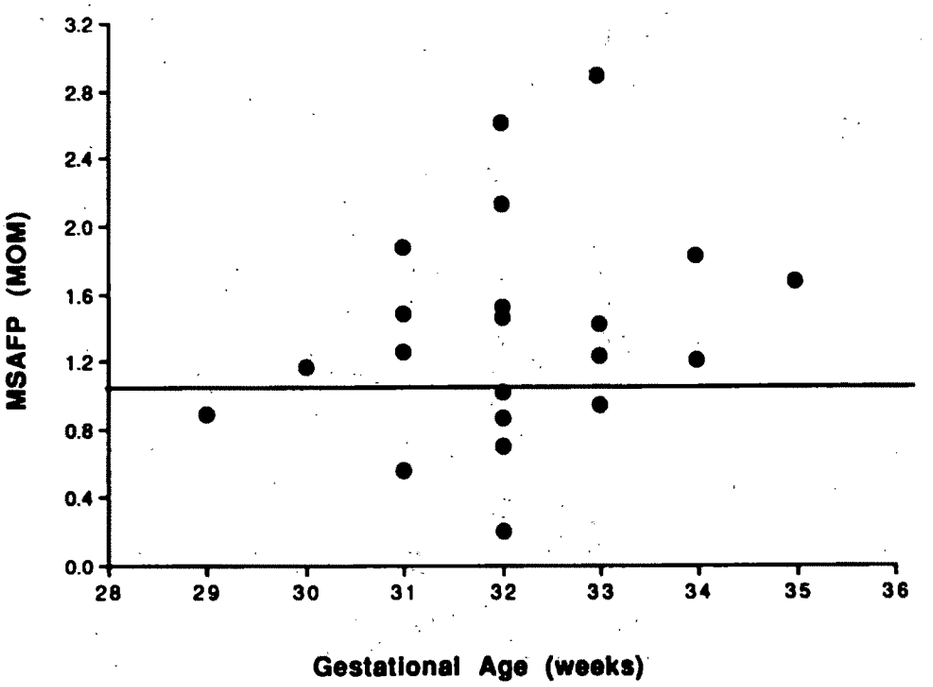

Fig. 4. Maternal serum AFP (MSAFP) values in women with preterm labor subsequently delivered before 37 weeks' gestation.

mal women who show unexplained second-trimester maternal serum AFP elevations. Although the prudent obstetrician will exercise due care and oversight, we believe it is premature to counsel such women that they are at increased risk of poor pregnancy outcomes such as perinatal death or low birth weight.

Third-trimester maternal serum AFP. Third-trimester maternal serum AFP assays were pursued over a decade ago but apparently were abandoned because of discrepant results. Our data indeed confirm that maternal serum AFP levels in the third trimester show greater variance than those in the early second

trimester. However, the variance is not so great that usefulness of third-trimester screening is precluded. Table III further suggests that late second-trimester and early third-trimester maternal serum AFP elevations could be predictive of pregnancy complications. Two of 24 pregnancies characterized by elevations showed fetal death; several other pregnancies showed other obstetric complications. In aggregate, Tables II and III suggest that maternal serum AFP elevations in both the second and third trimesters are useful yet independent of one another.

One way to verify the value of unexplained second-trimester elevations is by longitudinal analysis of maternal serum AFP later in pregnancy. One would predict that unexplained routine second-trimester (15 to 20 weeks' gestation) elevations in otherwise normal women would remain elevated during the late second-trimester and early third-trimester in those pregnancies manifesting an adverse perinatal outcome. If not, previous claims of a relationship between second-trimester elevations and adverse perinatal outcome might either be specious or merely confirmatory of information already known clinically. On the other hand, one could postulate that in certain conditions maternal serum AFP might be elevated in the second trimester but more nearly normal later in gestation as a result of changing placentation. Moreover, the test may be useful only during the time of gestation during which maternal serum AFP was rising (i.e., before 32 weeks' gestation).

Two approaches can help determine the significance of elevated second-trimester maternal serum AFP levels and the potential use of late second-trimester and early third-trimester levels. First, large scale longitudinal studies throughout pregnancy are obviously necessary. Second, cross-sectional studies should be pursued. Indeed, a cross-sectional approach is the basis for routine second-trimester (15 to 20 weeks' gestation) maternal serum AFP screening, and pragmatically would be the approach used clinically later in pregnancy. In Fig. 3 there is a tendency for women with preterm premature rupture of membranes, not yet manifesting labor, to show maternal serum AFP levels above the median. Fig. 4 shows an apparent association between elevated maternal serum AFP levels at 24 to 36 weeks' gestation and premature labor. Confirmation of these trends would suggest a diagnostic role for maternal serum AFP in the third trimester.

In conclusion, the value of unexplained second-trimester maternal serum AFP elevations in identification of pregnancies at risk of adverse outcomes other than neural tube defects seems worth pursuing. However, important issues are not being addressed, namely the extent to which ascertainment biases influence extant data, and the extent to which elevated maternal serum AFP levels contribute information different from that already known by clinically alert obstetricians. In our opinion, until these issues are addressed, aggressive (and expensive) perinatal surveillance programs should not be recommended for otherwise normal women with unexplained second-trimester (15 to 20 weeks' gestation) maternal serum AFP elevations. We propose that this issue can be resolved by determining the relationship between second- and third-trimester maternal serum AFP levels. Our preliminary data further indicate that late second-trimester and early third-trimester levels could be useful in identification of women with certain pregnancy complications.

Cardiac function in fetuses of type I diabetic mothers

Giuseppe Rizzo, MD,[a] Domenico Arduini, MD,[a] and Carlo Romanini, MD[b]
Rome and Ancona, Italy

Cardiac function was cross-sectionally studied by means of M-mode and Doppler echocardiography in 40 fetuses of mothers with well-controlled insulin-dependent diabetes at 20 to 38 weeks of gestation. These variables were measured: interventricular septal thickness, ratio between the peak velocities during early passive ventricular filling and active atrial filling at the level of the atrioventricular valves, peak velocities, and the time to peak velocity at the level of the ascending aorta and the pulmonary artery. The values obtained were compared with our reference limits for gestation. A significant increase of interventricular septal thickness that was unrelated to maternal glycosylated hemoglobin levels was evidenced. Early passive ventricular filling/active atrial filling ratios were significantly lower in fetuses of diabetic mothers than in control fetuses. These differences were significantly related to interventricular septal thickness. No significant modifications were found in either aortic or pulmonary peak velocities or in time to peak velocity values. These findings suggest that in spite of an adequate metabolic control an interventricular septal hypertrophy that affects cardiac diastolic function develops in fetuses of diabetic mothers. (AM J OBSTET GYNECOL 1991;164:837-43.)

Key words: Diabetes, fetal heart, echocardiography, Doppler ultrasonography, diastolic function

Although the existence of hypertrophic cardiomyopathy in infants of diabetic mothers has been extensively described,[1] few data currently are available on the development of this anomaly during intrauterine life.[2, 3] In this study M-mode and Doppler echocardiography was used to study cardiac function in fetuses of mothers with type I diabetes.

Material and methods

Patients. Forty-two women with type I insulin-dependent diabetes were evaluated in this study. Twenty-four women belonged to class B, 10 to class C, and 8 to class D, according to the modified White's classification.[4] All pregnancies were singleton and were accurately dated by early ultrasonographic examination. Diabetes was controlled by self-monitoring of blood glucose levels, and insulin adjustments were performed at the biweekly visit, if necessary, with the goal of maintaining the preprandial and postprandial blood glucose levels below 90 and 120 mg/dl, respectively. The obstetric characteristics of the patients are reported in Table I. At the time of echocardiographic examination the glycosylated hemoglobin (HbA_{1C}) was measured, and the results obtained were correlated with the echocardiographic findings. All patients gave informed consent to participate in the study. Each patient was included in the study only once.

Table I. Characteristics of 40 patients with type 1 diabetes considered for study

Age (yr, mean ± SD and range)	24.9 ± 4.4	(19-35)
Parity (mean ± SD and range)	1.3 ± 0.5	(0-4)
HbA_{1C} in first trimester (%, mean ± SD and range)	6.0 ± 1.0	(4.8-7.4)
HbA_{1C} at Doppler recording	5.7 ± 0.8	(4.5-6.9)
Gestational age at Doppler recording (wk, mean ± SD and range)	29.7 ± 4.8	(20-38)
Gestational age at delivery (wk, mean ± SD and range)	38.3 ± 1.9	(35-40)
Birth weight (gm, mean ± SD and range)	3353 ± 576	(2640-4220)
Large-for-gestational-age newborns (>90th percentile)	4 (10%)	
Fetal distress necessitating emergency cesarean section	9 (22.5%)	

Echocardiographic examination. Commercially available Ansaldo Hitachi Esacord 81 (Genoa) color Doppler equipment with 3.5 or 5 MHz convex probes was used for all measurements. The machine is equipped with a color flow mapping function, as well

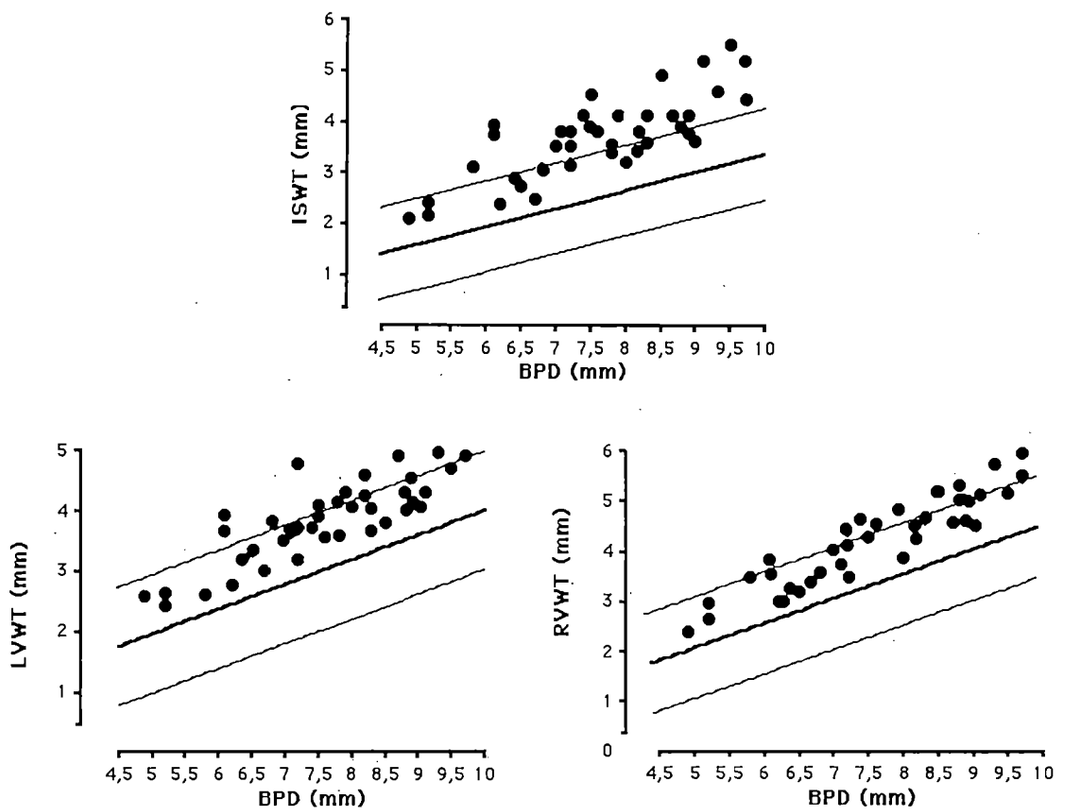

Fig. 2. ISWT, LVWT, and RVWT values obtained in fetuses of diabetic mothers, as plotted on our reference range (mean and 95% confidence intervals).

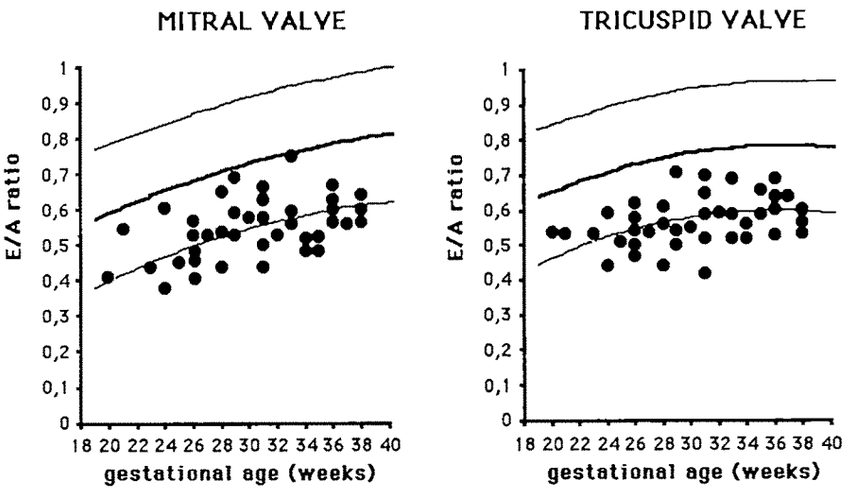

Fig. 3. Transtricuspid and transmitral E/A ratios obtained in fetuses of diabetic mothers, as plotted on our reference ranges for gestation (mean and 95% confidence intervals).

as a pulsed Doppler ultrasonography with a carrier frequency that ranges from 2.5 to 5 MHz.

The fetal heart was first examined with two-dimensional echocardiography, and two patients were excluded from the study because of congenital heart diseases (i.e., tetralogy of Fallot and atrioventricular canal). A subcostal four-chamber view of the fetal heart was obtained in the remaining 40 patients. The M-mode beam was directed perpendicular to the interventricular septum at the level of the atrioventricular valves, and images were recorded.[5] Velocity waveforms were then recorded at the level of the atrioventricular valves, ascending aorta, and pulmonary artery, according to previously reported techniques.[6, 7] Mitral and tricuspid valves were visualized from the apical four-chamber view, as were the aortic valve from the five-chamber view and the pulmonary valve from the short-axis view. The color flow mapping function was then superimposed, and the valve flow was evidenced. Care was taken to visualize the flow so that it was parallel to the Doppler beam. The pulsed Doppler sample volume was placed immediately distal to valve leaflets, and velocity waveforms were recorded. Recordings at a beam angle larger than 20 degrees were rejected.

Doppler and M-mode images were recorded on standard ½-inch videotape for subsequent analysis. Permanent records were obtained from the videotape by means of a strip chart recorder. Ten consecutive heart cycles were selected during periods of fetal rest without breathing movements, and the values measured were averaged. These variables were measured with the aid of a computer-interfaced digitizer pad (Cardio 800, Kontron, Oxford): (1) wall thickness during end diastole at the level of the interventricular septum (ISWT), left ventricle (LVWT), and right ventricle (RVWT)[5]; (2) tricuspid and mitral blood flow velocities during early ventricular filling (E wave) and during atrial systole (A wave)[6]; (3) the peak velocities of the aortic and pulmonary valves; (4) pulmonary and aortic time to peak velocity values, which were calculated as the time differences from the onset of the waveform to its peak velocity[7]; (5) heart rate. The ratios between E-wave and A-wave peak velocities (the E/A ratio) at the level of both atrioventricular valves were then calculated as indices of ventricular diastolic function.[6]

Data analysis. The variables measured were compared with our reference limits that were obtained from the cross-sectional study of 197 fetuses from normal pregnancies that were between 20 and 40 weeks' gestation. Because the size of the heart is better related to fetal dimension than to gestational age,[5] reference limits for ISWT, LVWT, and RVWT were constructed considering the fetal biparietal diameter as the independent variable. In addition, gestational age was used as the independent variable to calculate normative data for Doppler measurements.[6, 7]

Because all the variables considered change with gestation, the individual echocardiographic values observed in fetuses of diabetic mothers were also expressed as the number of standard deviations from the respective normal means for gestation (e.g., ΔISWT, Δmitral E/A ratio). A one-sample Student *t* test was used to compare echocardiographic parameters of control fetuses with those of fetuses of diabetic mothers, whereas the differences among diabetic fetuses were tested with the unpaired Student *t* test. Simple and multiple regression analyses were used to test the relationships between the variables considered. These analyses were performed on a Macintosh II (Apple Computers, Cupertino, Calif.) computer with the Stat View II statistical package (Abacus Concepts Inc., Berkeley, Calif.).

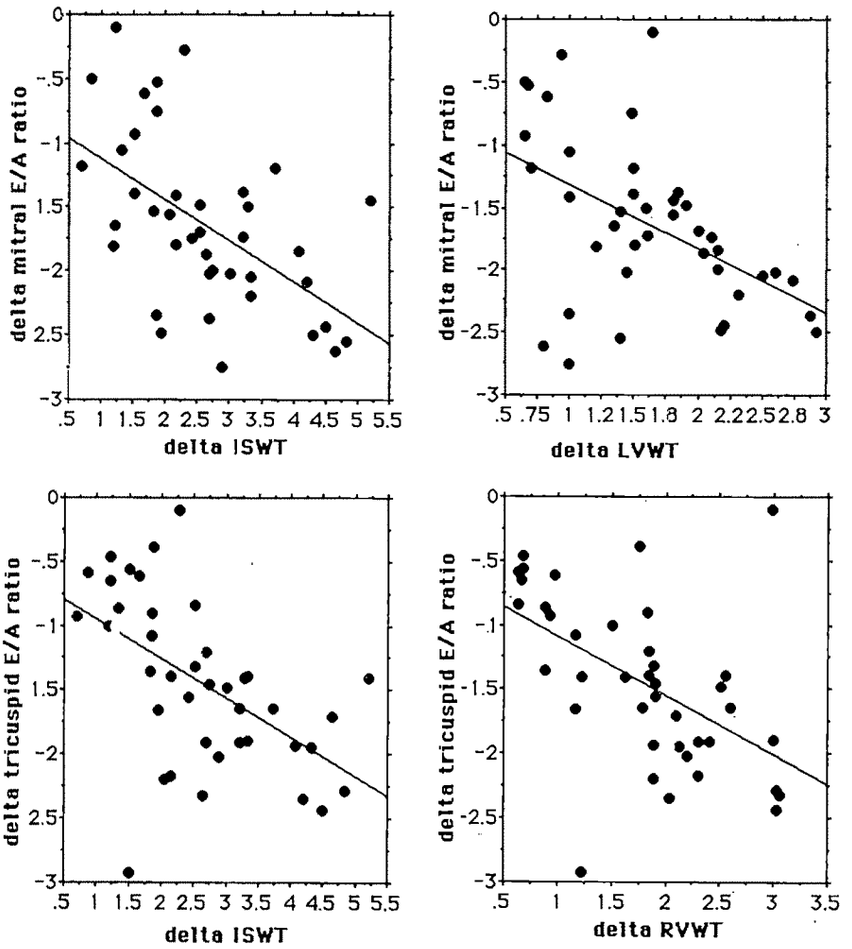

Fig. 4. Relationships between mitral E/A ratio with ISWT *(left)* and LVWT *(right)* and between tricuspid E/A ratio with ISWT *(left)* and RVWT *(right)*. All values are expressed as number of SDs by which they differed from the respective means for gestational age (Δ-values).

Results

Successful recordings were obtained in all cases at the level of the atrioventricular valves (Fig. 1). In 32 cases reliable data were obtained from all four cardiac sites, whereas fetal position did not allow successful recordings at the level of the pulmonary artery and ascending aorta, respectively, in three and five cases. At birth none of the infants had clinical signs of cardiomyopathy, with the exception of the two fetuses excluded for congenital heart diseases.

M-mode echocardiography. The ISWT values of fetuses of diabetic mothers were significantly higher (mean difference 2.632 SDs, $t = 16.437$, $p \leq 0.001$) when compared with our reference limits for gestation. Similar results were obtained when LVWT (mean difference 1.626 SDs, $t = 15.987$, $p \leq 0.001$) and RVWT (mean difference 1.790 SDs, $t = 15.201$, $p \leq 0.001$) values were considered (Fig. 2). However, there were no relationships between HbA_{1c} and ΔISWT ($r = 0.194$), ΔLVWT ($r = 0.123$), and ΔRVWT ($r = 0.106$) values. Furthermore no differences were found in M-mode parameters when fetuses of diabetic mothers assigned to White's class B were compared with those fetuses of mothers in classes C and D.

Diastolic function. In the fetuses of diabetic mothers the E/A ratio results were significantly lower at the level of both mitral valves (mean difference −1.634 SDs, $t = 15.414$, $p \leq 0.001$) and tricuspid valves (mean difference −1.449 SDs, $t = 14.038$, $p \leq 0.001$) when compared with the E/A ratios of control fetuses (Fig. 3). A significant negative relationship was found between Δ mitral E/A ratio and both ΔISWT (constant = −0.790, slope = −0.321, SD = 0.567, $r = 0.552$, $p \leq 0.001$) and ΔLVWT values (constant = −0.794, slope = −0.517, SD = 0.590, $r = 0.496$, $p \leq 0.002$) (Fig. 4) with a multiple r value of 0.601. Simi-

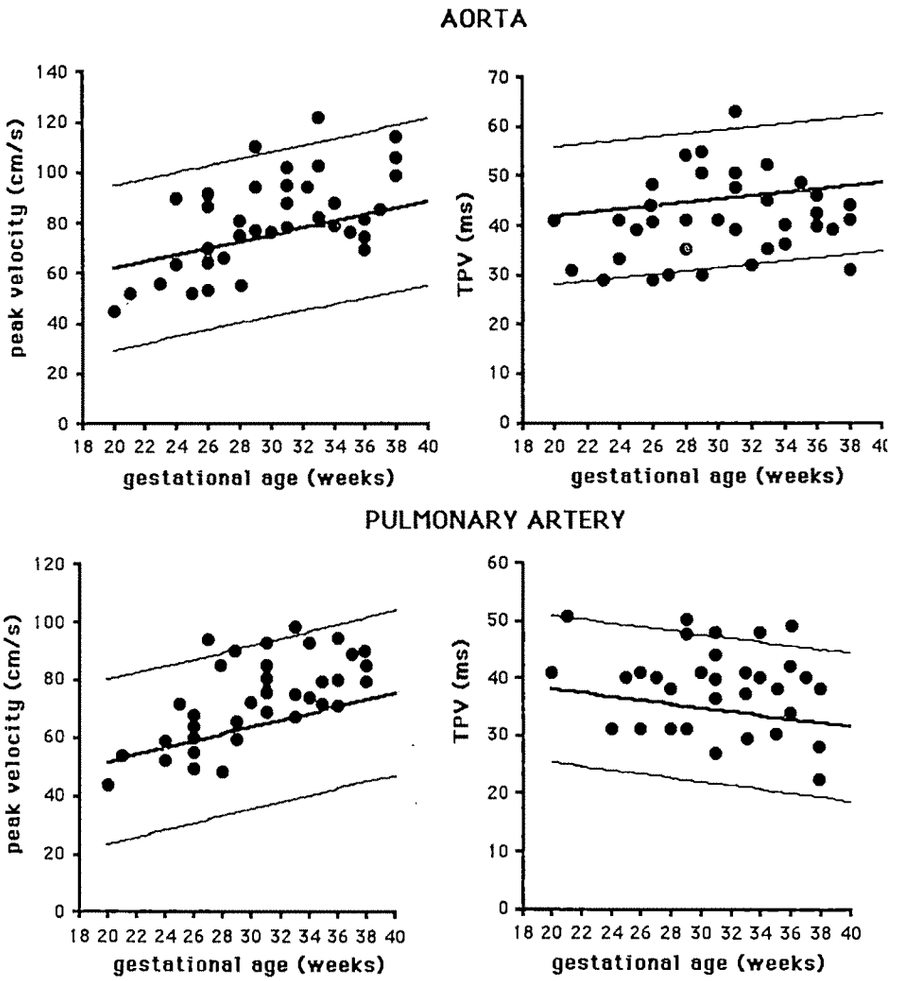

Fig. 5. Aortic *(top)* and pulmonary *(bottom)* peak velocity and time to peak velocity *(TPV)* values in fetuses of diabetic mothers, as plotted on our reference ranges for gestation (mean and 95% confidence intervals).

larly, Δ tricuspid E/A ratio results were negatively related to ΔISWT (constant = −0.643, slope = −0.306, SD = 0.556, $r = 0.541$, $p \leq 0.002$) and ΔRVWT values (constant = −0.629, slope = −0.458, SD = 0.564, $r = 0.491$, $p \leq 0.005$) (Fig. 4) with a multiple r value of 0.590. The HbA_{1c} value results were unrelated to mitral ($r = 0.141$) and tricuspid ($r = 0.152$) Δ E/A ratios. No significant differences were found in E/A ratios when fetuses were grouped according to White's class of the mother.

Systolic function. In Fig. 5 aortic and pulmonary values of peak velocity and time to peak velocity obtained in fetuses of diabetic mothers are plotted against our reference limits for gestation. No significant changes were evidenced and no significant correlations were found with ΔISWT, ΔRVWT, and ΔLVWT ($r < 0.116$), with HbA_{1c} ($r < 0.123$) values, with White's class of the mother.

Relations to pregnancy outcome. Nine fetuses required emergency cesarean section because of fetal distress (abnormal fetal heart patterns characterized by late or repetitive variable decelerations and/or loss of baseline variability) (Table I). When these fetuses were compared with the remaining fetuses of diabetic mothers studied, no significant differences were found in the cardiac parameters considered (Table II). Similarly, there were no differences when echocardiographic findings of large-for-gestational age fetuses (i.e., birth weight above the 90th percentile) were compared with those of appropriate-for-gestational-age fetuses (Table II).

Comment

A linear increase with fetal growth of both heart size and wall thickness has been evidenced in the human fetus.[5] Moreover, a concomitant improvement of the

cardiac performance has been described. The E/A ratio, a widely accepted index of ventricular diastolic function,[8] significantly increases during gestation at the level of both atrioventricular valves. These changes are believed to be secondary to the progressive maturation of ventricular compliance.[9] There is also an increase of aortic and pulmonary peak velocities and of left and right stroke volumes,[10] which suggests an improvement of ventricular systolic function with gestation. Previous studies have shown that in infants of diabetic mothers there is a hypertrophic cardiomyopathy that is characterized primarily by a significant thickening of the interventricular septum.[1, 11] Our data on a large series confirm previous sporadic reports[2, 3] that the increase of ISWT, LVWT, and RVWT is already established during intrauterine life. The absence of correlations between the HbA_{1c} values and the severity of cardiac wall thickness found in this investigation is in agreement with the results of neonatal studies[12] and suggests that in spite of adequate metabolic control during pregnancy, fetuses of diabetic mothers might experience an abnormal cardiac growth. However, there is no current account regarding whether the increase of cardiac wall thickness merely reflects the larger size of fetuses of diabetic mothers or whether it might also influence the fetal cardiac function. The lower E/A ratios at the level of both atrioventricular valves found in these fetuses might indicate an impaired ventricular diastolic function. The inverse relationships between the E/A values and both the interventricular septum and lateral ventricular wall thickness suggest that the abnormal cardiac thickening might impair ventricular compliance, which would affect the filling patterns of the ventricles. Previous microscopic studies on the heart in newborns of diabetic mothers corroborate this hypothesis by showing a disorganization of the myofibrils, which is similar to that present in adults with hypertrophic cardiomyopathy,[1, 13] a condition characterized by evident alterations of ventricular compliance and thus of Doppler-measured diastolic function.[14]

In spite of a ventricular hypercontractility reported in infants of diabetic mothers,[1] no significant modifications of systolic indices such as aortic and pulmonary peak velocities or time to peak velocity were evidenced in the fetuses examined. In adults diastolic dysfunction usually precedes systolic anomalies that appear later in the development of the myocardial disease.[15] Therefore it can be speculated that the fetuses studied have not reached a degree of cardiac impairment sufficient to affect systolic function. This hypothesis is supported by the data available on infants of diabetic mothers which show that echocardiographic indices of systolic function fall either in the normal range or above the normal range[1] and are usually abnormal only in newborns with clinical signs of cardiac impairment.[16]

In conclusion our data suggest that despite careful metabolic control of pregnancy, fetuses of diabetic mothers show an increased thickness of the interventricular septum and of the ventricular walls, which may be associated with abnormalities of diastolic function. Further longitudinal studies during the perinatal period are required to clarify the clinical significance of these changes of cardiac function and their sequelae during neonatal life.

Human placenta expresses endothelin gene and corresponding protein is excreted in urine in increasing amounts during normal pregnancy

Ariela Benigni, Biol.Sci.D.,[a] Flavio Gaspari, Chem.D.,[a] Silvia Orisio, Biol.Sci.D.,[a] Luca Bellizzi, Chem.,[a] Giuseppe Amuso, MD,[b] Tiziana Frusca, MD,[d] and Giuseppe Remuzzi, MD[a, c]

Bergamo and Brescia, Italy

Systemic and renal hemodynamic changes occurring in normal pregnancy have been attributed in part to altered vascular synthesis of vasodilatory prostaglandins. Besides vasodilatory substances, endothelium also generates vasoconstrictors, including endothelin. We evaluated the capacity of placental tissue from normal pregnant women to express endothelin gene and to generate endothelin. Placental tissue expressed a single 2.3 kb preproendothelin messenger ribonucleic acid and produced comparable amounts of endothelin 3, Big endothelin 1, and endothelin 1 and a minor quantity of endothelin 2. To investigate the possible influence of placental endothelin production on plasma levels of the peptide, plasma endothelin concentrations were measured in normal pregnant women at delivery and were found to be numerically higher than those measured in nonpregnant subjects. Urinary excretion of endothelin, taken as a marker of the renal synthesis of the peptide, tended to increase, although not significantly, in the first 14 weeks of pregnancy. This trend continued throughout pregnancy, resulting in a significant increase from the second trimester to delivery. (AM J OBSTET GYNECOL 1991;164:844-8.)

Key words: Endothelin gene expression in placenta, placenta endothelin production, plasma endothelin, endothelin urinary excretion in normal pregnancy

Normal pregnancy is associated with characteristic changes in systemic and renal hemodynamics. A substantial decrease in peripheral vascular resistance offsets increases in blood volume and cardiac output and results in a modest fall in blood pressure during the course of a normal pregnancy.[1] This change in blood pressure is maximal during the midtrimester[2] and tends to return to normal during the third trimester. Concomitant with systemic hemodynamic changes, an increase in renal plasma flow, associated with a rise in glomerular filtration rate, has been reported.[3] The intrarenal mechanisms responsible for the changes in renal plasma flow and glomerular filtration rate have been studied by micropuncture technique in the rat, which showed that the single-nephron glomerular filtration rate is increased as early as 5 to 12 days of gestation.[4] The decreased vascular tone and the modifications in renal hemodynamics occurring in pregnancy may be attributed in part to changes in the synthesis of endothelial-derived vasoactive substances. Thus in normal pregnancy systemic[5] and renal[6] synthesis of vasodilatory prostacyclin[7] is increased and may be responsible for the marked resistance to the pressor effects of angiotensin II.[8] Vascular endothelium generates vasodilators and vasoconstrictor substances, and a proper balance between vasodilators and vasoconstrictors may be crucial to the adaptive changes occurring in pregnancy. In this context the recent discovery that vascular endothelium produces endothelin, a 21 amino acid residue peptide with potent vasoconstrictor properties,[9] has prompted us to investigate whether normal placental tissue expresses the endothelin gene and generates endothelin peptides and whether endothelin is measurable in the plasma or is excreted in the urine during the course of normal pregnancy.

Material and methods

Study groups consisted of women attending the Obstetric Divisions of Ospedali Riuniti in Bergamo and Spedali Civili in Brescia. All subjects denied taking any drug for at least 14 days before the study.

Three groups of normotensive women were studied: Group 1 consisted of nine women in the first trimester

(0 to 14 weeks), group 2 was made up of seven women in the second trimester (14 to 28 weeks), and group 3 contained eight women admitted for routine delivery at 28 to 40 weeks' gestation. All women had blood pressure not exceeding 140/85 mm Hg, did not have significant proteinuria, and gave birth to a live infant of normal weight after 36 weeks' gestation. The placenta appeared normal in all cases. An additional group of nine nonpregnant women from the staff of the two divisions was studied as a control group.

Term placentas from five of the pregnant women were obtained at delivery and processed within 30 minutes from collection. A mixture of vaginal ($n = 3$) and cesarean section ($n = 2$) deliveries was studied. Placental tissues were separated, gently cut into small pieces, and washed repeatedly with phosphate buffer. A portion of the minced tissue was lysed in guanidium isothiocyanate, and total ribonucleic acid (RNA) was recovered by centrifugation through cesium chloride as previously described.[10] Poly(A) RNA was then selected by oligo (dT)-cellulose column chromatography.[11] Five micrograms of placental messenger RNA and 10 μg of endothelial cell total RNA from the human umbilical cord, taken as a positive control for endothelin gene expression, were then fractionated on 1.2% agarose gel with 6% formaldehyde and blotted onto synthetic membranes (Gene Screen Plus, New England Nuclear, Boston). Human preproendothelin probe was labeled by a random-primed labeling method with the use of (α-phosphorus 32)deoxycytidine triphosphate.[12] Membranes were hybridized with endothelin 1 complementary deoxyribonucleic acid labeled with phosphorus 32 and exposed to x-ray film for autoradiography.

To investigate the placental elution pattern of endothelin 1, 2, and 3 and Big endothelin 1, the tissue was frozen after collection, boiled for 10 minutes in 1 mol/L acetic acid to inactivate proteases, and then homogenized with an Ultra-Turrax (Janke & Kunkel GMBM & Co. KG, Staufen, Federal Republic of Germany) homogenizer in an ice bath for 60 seconds. After the addition of 0.5% Triton X-100 and 5000 counts/min of iodine 125–endothelin (Amersham International, Buckinghamshire, U.K.), the homogenate was shaken in an ice bath for 20 minutes, then centrifuged at 40,000 *g* for 30 minutes at 4° C. The supernatant was loaded into a Sep-pak C_{18} cartridge, which had been conditioned with 5 ml of methanol and 5 ml of water and preequilibrated with 5 ml of 1 mol/L acetic acid. After the sample was applied, the cartridge was washed with 5 ml of 1 mol/L acetic acid and the adsorbed material was eluted with 3 ml of acetonitrile/0.1% trifluoroacetic acid (65:35). Eluate was extracted with diethylether and the aqueous phase was subjected to reversed-phase high-performance liquid chromatography.

Extracted sample was chromatographed on a reversed-phase C_{18} column equilibrated with 0.1% trifluoroacetic acid. A gradient of acetonitrile was used at a flow rate of 1 ml/min. High-performance liquid chromatography fractions were collected and lyophilized, and the content of different endothelins was assayed in high-performance liquid chromatography fractions that coeluted with corresponding authentic standards. The protein content of placental tissue was determined by the method of Lowry et al.[13]

Blood was quickly mixed with ethylenediaminetetraacetate (2 mg/ml) and aprotinin (500 kallikrein inhibitor units per milliliter); plasma was separated by centrifugation at 1700 *g* for 15 minutes and immediately frozen at −20° C until assayed. Plasma samples (5 ml), spiked with 1000 counts/min of ^{125}I-endothelin, were applied to a Sep-pak C_{18} column, eluted as described for placental tissue, and lyophilized until assayed. Overnight urine samples were collected during 6 to 8 hours and frozen at −20° C until time of assay. Urine samples (5 ml) containing 1000 counts/min of ^{125}I-endothelin were run on a Sep-pak C_{18} disposable column that had been previously activated with 3 ml of 100% methanol, 3 ml of 10% methanol, 3 ml of 20% methanol, 3 ml of 85% methanol, and 4 ml of 10% methanol. The column was subsequently washed with 4 ml of 20% methanol, and elution was performed with 4 ml of 85% methanol. The elution fraction was lyophilized. The dried residue was stored at −20° C until assayed. The overall extraction recovery, as assessed by ^{125}I-endothelin, was 80% to 85% for placental tissue, 65% to 75% for plasma, and 70% to 85% for urine.

Extracted samples were resuspended in phosphate buffer (pH 7.2) containing 0.1% Triton X-100 and 0.3% albumin (radioimmunoassay buffer) immediately before the assay. Either standard peptides (endothelin 1, 2, or 3 or Big endothelin 1, Peptide Institute, Osaka) or unknown samples (100 μl) were incubated with 100 μl of the antiserum (for measurement of endothelin 1, 2, or 3: Peninsula Laboratories, Inc., Belmont, Calif.; for measurement of Big endothelin 1:Biomedica, Vienna) for 24 hours at 4° C. Then 12,000 counts/min of ^{125}I-endothelin or human ^{125}I-Big endothelin 1 (Amersham) (100 μl) was added and the incubation was prolonged for 24 hours at 4° C.

Separation of free from antibody-bound labeled peptides was achieved by addition of an immunoprecipitating mixture consisting of a sheep antirabbit immunoglobulin G and polyethylene glycol (500 μl) for 30 minutes at room temperature. Finally, 1 ml of phosphate buffer was added to stop the reaction and the immunoprecipitates were centrifuged at 1700 *g* for 20 minutes. Supernatants were removed by aspiration with a vacuum pump, and pellet radioactivity was detected by a γ-counter (Beckman, Irvine, Calif.). Results were

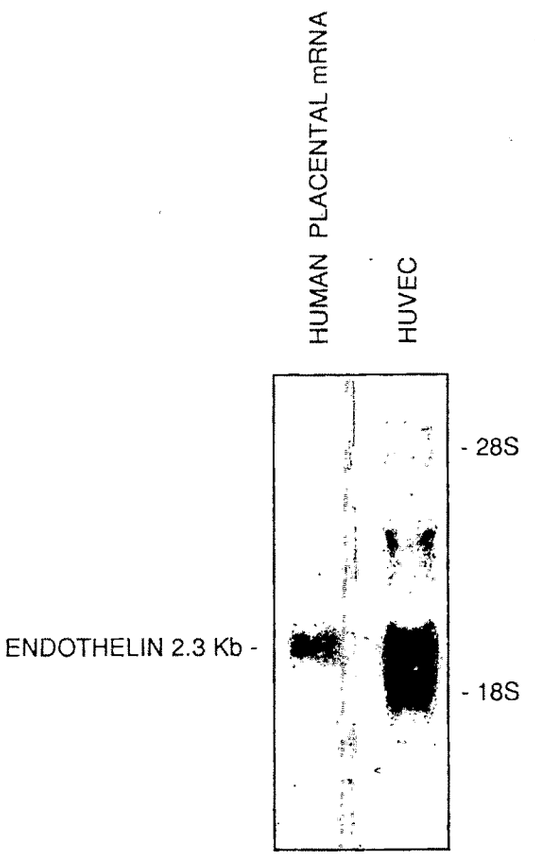

Fig. 1. Endothelin messenger RNA expression in placental tissue. RNA from umbilical vein endothelial cells *(HUVEC)* was used as positive control. Ribosomal RNAs (28S and 18S) were used as size markers.

expressed as picograms per milligram protein for placental tissue, picograms per milligram for plasma, and picograms per milligram creatinine for urine.

The minimum detectable concentration that could be measured was 0.4 pg per tube for endothelin 1, 2 pg per tube for endothelin 2, 0.8 pg per tube for endothelin 3, and 3.1 pg per tube for Big endothelin 1. Nonspecific binding did not exceed 2% of total radioactivity. For measurements of endothelin 1, 2, and 3 an anti–endothelin 1 antibody was used that cross reacts with endothelin 2 and 3, as follows: endothelin 1, 100%; endothelin 2, 46.9%; endothelin 3, 17%. Intraassay and interassay variability averaged 9% and 14% for all peptides measured. Validation of radioimmunoassay measurements was performed by comparison with different antisera and by recovery of cold endothelins added to placental tissue, plasma, and urine. Urine creatinine was measured by the alkaline picrate method.[14] All results are expressed by mean ± 1 SD. Data were analyzed by means of one-way analysis of variance with the use of Duncan's test for multiple comparison and the Student t test, as appropriate. All p values <0.05 were considered to indicate statistical significance.

Results

Normotensive pregnant subjects participating in this study ($n = 24$) ranged in age from 28 to 38 years. All women remained normotensive throughout pregnancy and had normal deliveries with a mean birth weight of 3.32 ± 0.35 kg. Placental tissue taken from these subjects constitutively expressed messenger RNA encoding preproendothelin. Fig. 1 shows a Northern blot demonstrating a single 2.3 kb preproendothelin messenger RNA expressed in placental tissue. This message was identical in size to that found in RNA obtained from human umbilical cord endothelial cells.

To investigate the placental endogenous content of endothelin 1, 2, and 3 and Big endothelin 1, placental tissue was extracted and subjected to high-performance liquid chromatography. The elution pattern of authentic standards separated by reversed-phase high-performance liquid chromatography is reported in Fig. 2, *a*. Three major peaks eluting from the high-performance liquid chromatography at the expected retention times of endothelin 3, Big endothelin 1, and endothelin 1 authentic standards were detected. Those values were on average 9.09 ± 0.01, 17.44 ± 3.50, and 12.20 ± 4.33 pg/mg of protein, respectively. A minor peak of immunoreactive material corresponding to endothelin 2 was observed (0.61 ± 0.14 pg/mg of protein) (Fig. 2, *b*). Endothelin plasma levels at delivery were numerically higher than those measured in normal nonpregnant subjects (0.35 ± 0.22 vs 0.24 ± 0.02 pg/ml), but the difference did not reach statistical significance. Urinary excretion of endothelin in the first trimester of pregnancy was numerically, although not significantly, increased (7.63 ± 4.31 pg/mg of creatinine) as compared with normal nonpregnant women (3.12 ± 2.65 pg/mg creatinine, Fig. 3). In the second and third trimesters urinary excretion of endothelin further increased, reaching statistically significant values (second trimester, 15.56 ± 4.00 pg/mg creatinine; third trimester, 19.57 ± 7.93 pg/mg creatinine; $p <$ 0.01) over those found in nonpregnant subjects and in the first trimester.

Comment

This study has documented that normal placental tissue expresses the endothelin gene and generates endothelin, a 21 amino acid peptide originally isolated from porcine aorta that induces hypertension in the rat when infused intravenously.[15]

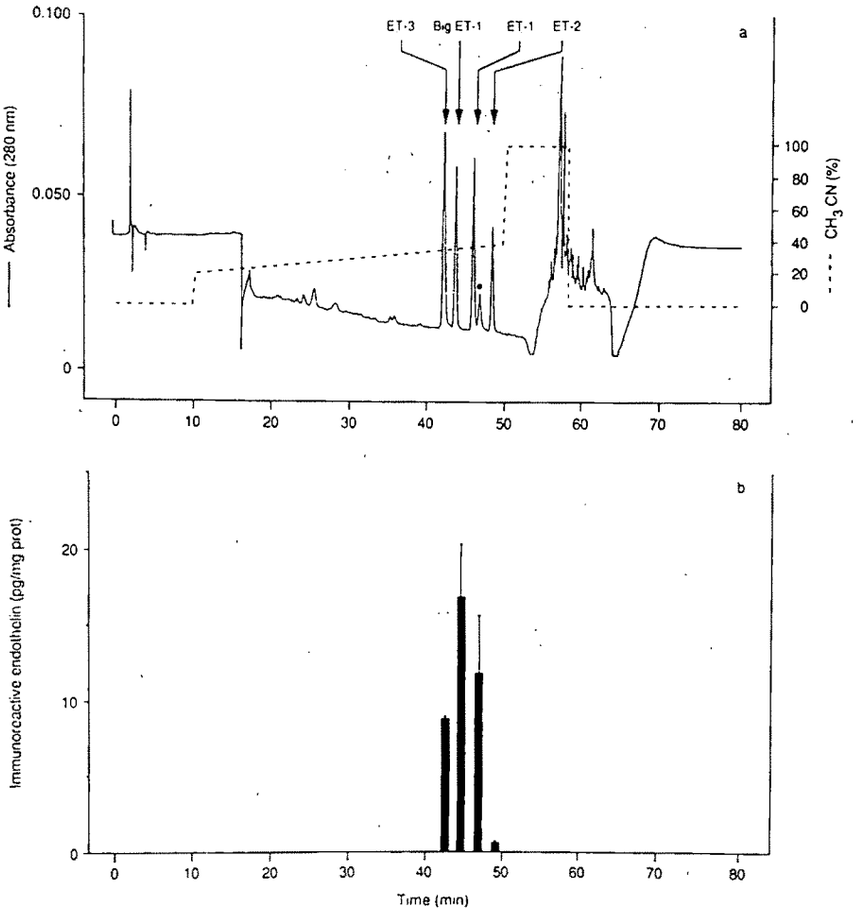

Fig. 2. a, Reversed-phase high-performance liquid chromatography elution profiles of the authentic standards of endothelin 3 *(ET-3)*, Big endothelin 1 *(Big ET-1)*, endothelin-1 *(ET-1)*, and endothelin-2 *(ET-2)*. *Asterisk*, Gradient peak. **b,** Immunoreactive profile of extract of human placenta. Each high-performance liquid chromatography fraction was concentrated by lyophilization and subjected to radioimmunoassay for *ET-3*, *Big ET-1*, *ET-1*, and *ET-2*.

Our results showed a numeric tendency for endothelin plasma levels to increase in pregnancy as compared with normal nonpregnant women, but the difference did not reach statistically significant values. These findings are in keeping with the majority of the data available, that circulating levels of endothelin are very low,[16, 17] suggesting that endothelin is not a circulating hormone but probably acts as a local regulator of blood supply to the various tissues.

We also wanted to investigate whether the renal synthesis of endothelin is modified in pregnancy. If so, it would have a major impact on the adaptation of renal circulation in pregnancy. Previous studies in experimental animals have documented that urinary excretion of endothelin may reflect renal synthesis of the hormone because labeled endothelin infused into systemic circulation of normal rat is excreted only in the

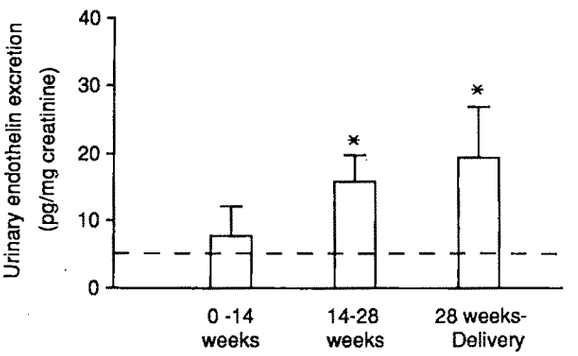

Fig. 3. Urinary excretion of endothelin in pregnant subjects throughout gestation. *Hatched line* represents upper 95% confidence limit of urinary endothelin excretion in normal nonpregnant women. *Asterisk*, $p < 0.01$ versus nonpregnant subjects and women in first trimester of pregnancy.

urine in negligible amounts. These results show that urinary excretion of endothelin progressively increased during normal pregnancy, reaching values statistically higher than in nonpregnant women at 14 to 28 weeks' gestation and increasing further thereafter.

Although there is no direct evidence that changes in endothelin renal synthesis are causally related to changes in renal hemodynamics, these results raise the possibility that renal endothelin acts as a local hormone to counteract the action of vasodilatory substances, such as prostacyclin and prostaglandin E_2 that markedly increase during normal pregnancy.[5, 6, 18] Endothelin potently stimulates the metabolism of arachidonic acid in various systems[19, 20]; therefore the possibility that changes in prostacyclin and prostaglandin E_2 are in fact mediated by endothelin can also be considered.

Further studies are needed to clarify the role of endothelin in the pathophysiologic characteristics of normal pregnancy and to establish whether the most common complications of pregnancy, such as hypertension and preeclampsia, are related to changes in endothelin biosynthesis or metabolism.

We are deeply indebted to Dr. Engelbert Hartter (2nd Department Internal Medicine, University of Vienna) for his cooperation, which allowed us to set up endothelin measurements in our Institute. We acknowledge Dr. Alessandro Rambaldi for helpful criticism and discussion. This study was possible because of the cooperation of Dr. Enio Cappato, Chief of the Division of Obstetrics and Gynecology, Ospedali Riuniti di Bergamo, and of Professor Attilio Gastaldi, Chief of the Obstetrics and Gynecology Clinic, University of Brescia.

Combination antimicrobial therapy in the treatment of acute pelvic inflammatory disease

Daniel V. Landers, MD,[a] Pal Wolner-Hanssen, MD,[b] Jorma Paavonen, MD,[b] Edwin Thorpe, MD,[b] Nancy Kiviat, MD,[b] Marilyn Ohm-Smith, MS,[a] James R. Green, MD,[a] Julius Schachter, PhD,[a] King K. Holmes, MD, PhD,[b] David A. Eschenbach, MD,[b] and Richard L. Sweet, MD[a]

San Francisco, California, and Seattle, Washington

We compared the clinical and microbiologic efficacy of two broad-spectrum combination antimicrobial regimens in the treatment of 148 patients with acute pelvic inflammatory disease. Patients were randomized to inpatient treatment with either cefoxitin and doxycycline (n = 75) or clindamycin and tobramycin (n = 73). These antibiotics were administered intravenously for at least 4 days, and up to 48 hours beyond defervescence. Patients were discharged on a regimen of oral doxycycline or clindamycin in accordance with the intravenous regimen to complete a total duration of therapy of 2 weeks. *Neisseria gonorrhoeae* (53%) and *Chlamydia trachomatis* (31%) were the microorganisms that were isolated most frequently from the genital tract of enrolled patients. At follow-up, *N. gonorrhoeae* was isolated in two patients, and *C. trachomatis* was isolated in none. The overall initial favorable response rate to combination antimicrobial therapy was 98.5% (130/132) in patients with uncomplicated pelvic inflammatory disease and 81% (13/16) in patients with pelvic inflammatory disease that was complicated by tuboovarian abscess. A > 70% decrease in abdominal tenderness score occurred in 89% of 111 patients within 6 weeks of hospital discharge. There were no significant differences between antibiotic treatment groups in any response categories or in toxicity. During the initial hospitalization, five patients (three with tuboovarian abscess, one with a pyosalpinx, and one with intractable acute and chronic pelvic inflammatory disease) required surgical intervention. These results support the recommendation to use broad-spectrum combination antimicrobial therapy for the treatment of acute pelvic inflammatory disease. (Am J Obstet Gynecol 1991;164:849-58.)

Key words: Pelvic inflammatory disease, acute salpingitis, pelvic infections, sexually transmitted diseases

The variety of microorganisms that cause acute pelvic inflammatory disease has been well-documented in numerous reports.[1-5] Microorganisms most commonly isolated from the upper genital tract of patients with acute pelvic inflammatory disease include *Chlamydia trachomatis, Neisseria gonorrhoeae, Escherichia coli, Bacteroides bivius,* and peptostreptococci. Awareness of the complex microbiologic features of acute pelvic inflammatory disease resulted in concern that single-agent antimicrobial therapy may not be effective in treating all patients with the disease. Cephalosporins and aminopenicillins have been the most common single drugs given to patients hospitalized for pelvic inflammatory disease.[6] These drugs are effective against gonococci; however, an intravenous cephalosporin regimen failed to eradicate *C. trachomatis* in the majority of patients with acute chlamydial pelvic inflammatory disease.[7] Tetracycline, the drug of choice for *C. trachomatis,* is not effective in treating *N. gonorrhoeae.* It became obvious that no single drug was effective against the broad range of potential pathogens in pelvic inflammatory disease. This was supported by the observation of Thompson et al.[8] of clinical failure rates of 14% to 19% with single-agent outpatient therapy with ampicillin or tetracycline in the treatment of acute pelvic inflammatory disease. Thus, in 1982, 1985, and 1989, the Centers for Disease Control recommended combination antimicrobial therapy for pelvic inflammatory disease because of its polymicrobial nature.[9-11] While several combination regimens provided broad-spectrum activity in vitro and offered coverage for the wide range of expected pathogens, none had been adequately evaluated for clinical efficacy in the treatment of pelvic inflammatory disease. The recommendations of the

Centers for Disease Control included examples of two combination regimens for hospitalized women with pelvic inflammatory disease: (1) cefoxitin plus doxycycline and (2) clindamycin plus gentamicin. Recently, Walters et al.[12] reported equal efficacy on comparing clindamycin and gentamicin with cefoxitin and doxycycline. Soper and Despress[13] had similar findings when they compared clindamycin and amikacin with cefoxitin and doxycyline.

This study was undertaken as a prospective, randomized, unblinded clinical trial to compare the antimicrobial and clinical efficacy of the combination regimens listed in the Centers for Disease Control guidelines, for the therapy of hospitalized patients with acute pelvic inflammatory disease.

Material and methods

Population. Eligible participants in the study were women older than 16 who had been admitted to the San Francisco General Hospital or to the Harborview Medical Center in Seattle, Washington, with abdominal pain. These patients were thought to have acute pelvic inflammatory disease. Excluded were patients with an allergy to any of the four antibiotics involved in the trial, pregnant women, or those with a history of having received antibiotic therapy within 2 weeks before admission to the study. Also excluded were patients with a history of pelvic surgery, abortion, uterine curettage, or delivery within 6 weeks of admission. The study was reviewed and approved by the institutional review boards at both hospitals that were involved in patient recruitment. Written informed consent was obtained from all patients before enrollment.

Pretreatment evaluation. All patients enrolled had either laparoscopically confirmed salpingitis[14] or histologically confirmed plasma cell endometritis[15] or they met previously published criteria for the noninvasive diagnosis of salpingitis.[16] These criteria include direct abdominal tenderness, cervical motion tenderness, and adnexal tenderness, plus one or more of the following: temperature ≥38° C, peripheral blood leukocytosis white blood cell count >10,500 mm^3, purulent material or culdocentesis, evidence of pelvic abscess on ultrasonography or pelvic examination, evidence of gonococcal or chlamydial cervicitis (by positive monoclonal antibody test or by Gram's stain showing gram-negative intracellular diplococci), or mucopurulent cervicitis as previously defined.[17]

Pretreatment laboratory tests included a complete blood count; a platelet count; serum electrolyte, creatinine, and blood urea nitrogen tests; liver function tests; a serum pregnancy test; blood cultures; and urinalysis. Cervical cultures were obtained for *N. gonorrhoeae, C. trachomatis, Mycoplasma hominis,* and *Ureaplasma urealyticum.* Endometrial cultures were obtained for these agents and for other facultative and anaerobic microorganisms. Women who underwent laparoscopy also had specimens obtained from the fallopian tubes and cul-de-sac fluid for culture of these microorganisms. Ultrasonographic examination was performed on all patients with adnexal masses, a slow clinical response, or an indication of tuboovarian abscess. Complex adnexal masses >4 cm were judged to be consistent with tuboovarian abscess.

Microbiology. Endocervical specimens for *C. trachomatis* were obtained via either cotton-tipped swabs or calcium alginate swabs. These specimens were taken from lots that were pretested and found to be nontoxic for *C. trachomatis.* The swabs were placed in antibiotic containing minimal essential medium or phosphate sucrose buffer and refrigerated for transport to the laboratory within 16 hours after collection. To test for *N. gonorrhoeae,* specimens from the endocervix were obtained with a Dacron or cotton-tipped swab and plated directly onto modified Thayer-Martin agar plates. These specimens were held at 35° C in a candle jar until they were transported to the laboratory (within 6 hours of collection), where they were incubated at 35° C in 5% carbon dioxide. Endocervical *M. hominis* and *U. urealyticum* specimens were obtained via a Dacron swab, which was immediately inoculated to a A7B agar plate and U9B broth. These specimens were held in a candle jar at 35° C until they were transported to the laboratory (within 6 hours of collection), where the A7B agar plate was incubated at 35° C in 5% carbon dioxide. The U9B broth was incubated at 35° C in room air. Endometrial brush or biopsy samples were divided under sterile conditions. One part was processed for *C. trachomatis* isolation, and the other was processed for the isolation of facultative and anaerobic organisms.

Specimens for *C. trachomatis* isolation were inoculated onto monolayers of McCoy cells by centrifugation. The cycloheximide-treated cells were cultured for 65 hours, and then examined for inclusions by iodine staining or immunofluorescence. Specimens were processed for isolation of facultative organisms by inoculation onto the following media, which were incubated in 5% carbon dioxide at 35° C: trypticase soy agar with 5% sheep blood, chocolate agar, CNA agar with 5% human blood, modified Thayer-Martin agar, and CNA agar with 5% sheep blood. These plates were examined two to three times over a 3- to 4-day period. *N. gonorrhoeae* and facultative bacteria were identified by standard methods.[18] Specimens processed for anaerobic growth were inoculated into Brucella agar that was supplemented with 5% sheep blood, vitamin K, and hemin, CNA agar with 5% sheep blood, kanamycin-vancomycin laked blood (LKV) agar, and chopped meat carbohydrate broth. Specimens were incubated at 35° C in either a GasPak jar (BBL, Cockeysville, Md.) or an anaerobic

chamber (Coy Manufacturing, Ann Arbor). Anaerobic microorganisms were identified via gas-liquid chromatography and prereduced anaerobically sterilized media.[19] Identification of colonies of genital mycoplasmas was based on colony morphologic features. Dark brown colonies on A7B agar which indicated hydrolysis of urea, were identified as *U. urealyticum*. In the U9B broth the presence of *U. urealyticum* was confirmed by a color change from yellow to pink. Identification of *M. hominis* was based on the "fried egg" appearance of colonies on A7B agar and failure to hydrolyze urea.

Tenderness scoring. Abdominal and pelvic examinations were scored prospectively at Harborview Medical Center via a modification of the scoring system described by McCormack et al.[20] In this scoring system 0 is absent, 1 is minimal, 2 is moderate, and 3 is severe. A score of 0 to 3 was assigned for direct tenderness and for rebound tenderness of the right and left upper and lower abdominal quadrants (total possible score = 24). In addition, pain with cervical motion, uterine tenderness, and left and right adnexal tenderness were scored from 0 to 3 (total possible score = 12). Finally, right and left adnexal masses were scored (total possible score = 6). In the scoring of masses, 0 is no mass, 1 is mass <2 cm, 2 is mass 2 to 5 cm, and 3 is mass >5 cm. Thus the maximum possible score on the examination was 42. Whereas it was not part of the initial design, the same system was adapted for retrospective analysis of abdominal and pelvic examination of patients at San Francisco General Hospital.

Treatment regimens. Patients were randomly assigned to one of two treatment regimens. One group received cefoxitin, 2 gm intravenously every 6 hours, plus doxycycline, 100 mg intravenously every 12 hours. The other group received clindamycin, 600 mg intravenously every 6 hours, plus tobramycin 2.0 mg/kg intravenously for one dose, followed by 1.5 mg/kg intravenously every 8 hours. All intravenous antibiotics were continued for a minimum of 4 days and for at least 48 hours after disappearance of fever. Patients that were afebrile on admission were treated for a minimum of 4 days in the hospital for at least 24 hours beyond the adequate relief of pain and tenderness which allowed patients to return to a normal life-style without surgical intervention. After discharge from the hospital, either oral doxycycline, 100 mg twice daily, or oral clindamycin, 450 mg four times daily, was continued to complete a total of 14 days of treatment.

Follow-up evaluation. Patients were interviewed and examined both at hospital discharge and at 2 to 6 weeks after initial enrollment. Cervical cultures were repeated at each follow-up visit. An initial favorable response was defined as a patient who was afebrile and did not need surgical intervention.

Statistical analysis. Discrete variables were analyzed with a standard χ^2 test or two-tailed Fisher's exact when cell values were <5. Continuous variables were analyzed with the unpaired t test. All p values of <0.05 were considered statistically significant.

Results

Patient characteristics. Total enrollment in this study included 102 patients, 14 of which could not be evaluated. Reasons for exclusion were incorrect diagnosis that was discovered at laparoscopy or laparotomy (i.e., ectopic pregnancy, endometriosis, appendicitis) or refusal of the patient to remain hospitalized long enough to complete treatment.

There were 148 evaluable patients—89 at San Francisco General Hospital and 59 at Harborview Medical Center. The diagnosis of acute pelvic inflammatory disease was made by laparoscopy in 43 patients, by endometrial biopsy in another 13, and by clinical diagnosis in the remaining 92 patients. Seventy-five of the 148 patients enrolled were treated with cefoxitin in combination with doxycycline, and 73 were treated with clindamycin in combination with tobramycin.

The demographic and historic data on sexual habits, contraceptive methods, and sexually transmitted diseases are summarized in Table I. There were no significant differences between treatment groups for any of the variables listed. There were also no differences in any of the variables between the patient populations at San Francisco General Hospital and those at Harborview Medical Center, with the exception of previously identified chlamydial infection. This infection was reported significantly more often by Harborview Medical Center (10/46, 22%) than by San Francisco General Hospital (4/89, 5%) (population $p < 0.01$).

Temperature at admission was ≥38° C in 55 (38%) of 145 patients; the overall mean temperature at admission was 37.6 ± 0.7° C. The white blood cell count was increased (>10,500/mm^3) in 97 (67%) of 145 patients; the mean white blood cell count was 12,700/mm^3 ± 4500/mm^3. Erythrocyte sedimentation rate was elevated (>20 mm/hr) in 82 (57%) of 143 patients; the mean erythrocyte sedimentation rate was 32.5 ± 25.9 mm/hr. There were no differences in admission temperature, white blood cell count, or erythrocyte sedimentation rate between those with laparoscopic diagnosis and those without that diagnosis. There were no differences between study centers San Francisco General Hospital vs Harborview Medical Center in these values. There also were no differences in these values between treatment groups, with the exception of the mean erythrocyte sedimentation rate, which was higher in the clindamycin-tobramycin group than in the cefoxitin-doxycycline group (38.4 vs 27.7 mm/hr; $p < 0.03$), because of two very high erythrocyte sedimentation rate values. Median erythrocyte sedi-

mentation rate values were not significantly different (30 vs 22 mm/hr).

Clinical response. The criteria for a satisfactory initial clinical response which were defined as an improvement of admitting signs and symptoms, included abdominal-pelvic pain, fever, and pelvic tenderness. An initial satisfactory clinical response occurred for 143 (97%) of 148 patients. The diagnosis of tuboovarian abscess was made by clinical examination with confirmation by ultrasonography or by either laparoscopy or laparotomy. A satisfactory rate of response was documented for 130 (98.5%) of 132 patients who had uncomplicated pelvic inflammatory disease and for 13 (81%) of 16 patients with tuboovarian abscess (NS). One of these patients underwent a primary laparoscopic drainage of the abscess at the time antibiotic therapy was initiated; therefore a satisfactory response was documented for 12 (80%) of 15 patients with abscesses who had received antibiotics alone. There were no differences in the response rate between antibiotic treatment groups for patients with either acute uncomplicated pelvic inflammatory disease or acute pelvic inflammatory disease with tuboovarian abscess (Table II).

Five patients needed surgery during the initial hospitalization. Two of these patients from the cefoxitin-doxycycline group had tuboovarian abscess. Three patients were from the clindamycin-tobramycin group-one had a tuboovarian abscess, one had pyosalpinx, and one had chronic persistent pelvic inflammatory disease.

Five patients returned with recurrent signs and symptoms of pelvic inflammatory disease within 6 weeks of discharge; three had been treated with cefoxitin-doxycycline, and two had received treatment with clindamycin-tobramycin. It was not possible to determine if these patients were reinfected or if they experienced recurrence or a recrudescence of the initial infection. None of the five had a positive culture for *C. trachomatis* or *N. gonorrhoeae* at the time of the recurrence of signs and symptoms of pelvic inflammatory disease.

The mean tenderness score on admission was 17.9 ± 5.9. No difference was found in initial mean tenderness

Table II. Favorable initial clinical response to indicated therapy

Diagnosis	*Cefoxitin-doxycycline*	*Clindamycin-tobramycin*	*Total*
Acute pelvic inflammatory disease	66/66 (100%)	64/66 (97%)	130/132 (98.5%)
Tuboovarian abscess	7/9 (78%)	6/7* (86%)	13/16 (81%)
TOTAL	73/75 (97%)	70/73 (96%)	143/148 (97%)

There were no significant differences in the clinical responses between treatment groups.
*One patient in this group underwent laparoscopic drainage of an abscess as a part of the initial therapy.

scores between treatment groups. No significant differences were found in tenderness scores, and whether the scores were obtained prospectively made no difference. Follow-up tenderness scores were available on the day of discharge and 2 to 6 weeks after enrollment in the studies. A >70% decrease in tenderness score was noted in 99 (89%) of 111 patients 2 to 6 weeks after treatment. Only five patients showed <20% improvement in tenderness score, and four of these underwent surgical intervention. There was no significant difference between treatment groups with respect to improvement in tenderness scores.

Of the 57 patients prospectively scored for tenderness at Harborview Medical Center, 38 (67%) of 57 had >70% reduction in tenderness at the time of discharge (Table III). A ≥70% reduction in tenderness was achieved for 12 (75%) of 16 patients, who initially had <70% reduction in tenderness at discharge and were reevaluated 2 to 4 weeks after the conclusion of therapy. However, of 31 patients considered cured at discharge (>70% reduction in tenderness score at discharge) and who were later reevaluated, increased tenderness developed in six and they were then considered only improved (<70% and >20% reduction in tenderness score) 2 to 4 weeks after therapy. There were no differences in the follow-up tenderness scores between antibiotic treatment groups.

Microbiologic features. The microorganisms most frequently isolated from study patients were *C. trachomatis* and *N. gonorrhoeae*. Of the 136 patients from whom both endocervical and endometrial cultures were obtained, *C. trachomatis* was isolated from 42 (31%) and *N. gonorrhoeae* from 72 (53%). At least one of these two types of sexually transmitted microorganisms was isolated from 92 (68%) of the study patients, and both types of microorganisms were isolated from 22 (16%) of 136 patients. *C. trachomatis* was recovered from the endometrium in 24 (69%) of 35 patients with documented endocervical *C. trachomatis* infection. An additional three patients had positive endocervical cultures, but no endometrial cultures were done. Conversely, this microorganism was isolated from the endocervix in 27 (90%) of 30 patients who had positive endometrial cultures for *C. trachomatis*. *N. gonorrhoeae* was recovered from the endometrium of 56 (79%) of the 71 patients with positive results for *N. gonorrhoeae* on endocervical cultures. Another eight patients with endocervical *N. gonorrhoeae* did not have endometrial culture results. Only one of the 57 patients with positive endometrial cultures for *N. gonorrhoeae* had a negative endocervical culture for this organism. Two additional positive endometrial cultures for *N. gonorrhoeae* were obtained in patients without endocervical *N. gonorrhoeae* cultures.

C. trachomatis was isolated from the fallopian tubes of 5 (12%) of 43 patients from whom pretreatment tubal cultures were obtained at laparoscopy and from two of the nine patients with *C. trachomatis* in the endometrium. Four of 17 patients with endocervical *C. trachomatis* infection who underwent pretreatment tubal cultures had documented tubal *C. trachomatis* infection. One patient with tubal *C. trachomatis* infection had a negative endocervical culture for this organism. *N. gonorrhoeae* was isolated from the fallopian tubes in 16 (37%) of 43 patients, all 16 of whom also had *N. gonorrhoeae* in endometrial and endocervical cultures. There was no significant correlation between treatment failure and the organisms isolated from either the fallopian tubes or the endometrium.

Results of cultures for *C. trachomatis* and *N. gonorrhoeae*, with respect to both treatment centers and antibiotic treatment groups, are summarized in Table IV. Both *C. trachomatis* and *N. gonorrhoeae* were isolated from the endocervix significantly more often from patients enrolled at Harborview Medical Center than from patients enrolled at San Francisco General Hospital. Patients enrolled at Harborview Medical Center were also more likely than patients at San Francisco General Hospital to have *N. gonorrhoeae* isolated from the endometrium ($p < 0.01$), but there was no significant difference between treatment centers in the rate of *C. trachomatis* isolation from the endometrium. There were no differences between antibiotic treatment groups in isolation rates of either *C. trachomatis* or *N. gonorrhoeae* from the endocervix or endometrium.

Numerous facultative and anaerobic microorganisms were isolated from endometrial specimens, and such microorganisms were isolated less often from fallopian tube specimens. The mean number of these microorganisms recovered from endometrium was 4.5. The

Table III. Reduction in prospective tenderness scores with antibiotic treatment alone

	>70% Reduction at discharge	*<70% and >20% Reduction at discharge; ≥70% reduction at 2-4 wk*	*Total with ≥70% reduction*
Cefoxitin-doxycycline	19/28	3/6*	22/28† (79%)
Clindamycin-tobramycin	19/29	9/10*	28/29 (97%)
TOTAL	38/57 (67%)	12/16 (75%)	50/57 (88%)

*Cases with <70% reduction in tenderness score at discharge who returned for the 2 to 4-week follow-up and who had ≥70% reduction in tenderness score at 2 to 4 weeks.

†In 28 patients treated with cefoxitin-doxycycline, reduction in tenderness score was reached in at least 22. Three patients who had no improvement at the time of discharge were not seen at follow-up.

Table IV. Comparisons of chlamydial and gonococcal isolates between treatment centers and between study groups

	San Francisco General Hospital	*Harborview Medical Center*	*p Value*	*Cefoxitin-doxycycline*	*Clindamycin-tobramycin*	*p Value*
Endocervix						
C. trachomatis	14/89 (16%)	24/59 (41%)	0.001	17/76 (22%)	21/73 (29%)	0.5
N. gonorrhoeae	40/87 (46%)	38/57 (67%)	0.02	39/74 (53%)	39/72 (54%)	1.0
Endometrial						
C. trachomatis	19/89 (21%)	11/49 (22%)	0.9	10/70 (14%)	20/68 (29%)	0.05
N. gonorrhoeae	31/89 (35%)	28/47 (60%)	<0.01	33/68 (49%)	26/68 (38%)	0.3

most common pathogens isolated from the endometrium (other than *C. trachomatis* or *N. gonorrhoeae*) were *Bacteroides* species ($n = 75$) (*B. bivius* ($n = 41$), *B. capillosus* ($n = 22$), *B. disiens* ($n = 12$), *Peptostreptococcus anaerobius* ($n = 47$), *P. asaccharolyticus* ($n = 46$), *P. tetradius* ($n = 20$), *P. prevotii* ($n = 16$), *Gardnerella vaginalis* ($n = 61$), coagulase-negative staphylococci ($n = 39$), nonhemolytic streptococci ($n = 27$) and α-hemolytic streptococci ($n = 19$).

Follow-up cultures for *C. trachomatis* and/or *N. gonorrhoeae* that were obtained 2 to 4 weeks after the completion of therapy were negative from 86 of 88 patients who initially had these organisms. One patient treated with cefoxitin-doxycycline was clinically and microbiologically cured at the 2-week follow-up visit but had positive culture for *N. gonorrhoeae* at the 6-week visit after sexual contact with a new sex partner. The other patient showed clinical improvement after intravenous treatment with cefoxitin-doxycycline, but culture was positive for *N. gonorrhoeae* and she had pain and tenderness at the 2-week follow-up visit. The first case probably represents reinfection; however, the second case represents possible persistent infection. Of patients with pretreatment *C. trachomatis* infection, none of 19 in the cefoxitin-doxycycline group and none of 20 in the clindamycin-tobramycin group had *C. trachomatis* that was isolated after therapy had concluded.

Mycoplasma hominis was isolated from 22 (36%) of 62 pretreatment endometrial cultures and from 12 (19%) of 63 posttreatment cultures. There was no difference between treatment groups in the proportion with pretreatment *M. hominis*; however, posttreatment isolation of *M. hominis* occurred in 12 of 34 patients in the cefoxitin-doxycycline group and in none of 29 patients in the clindamycin-tobramycin group ($p < 0.01$).

Adverse effects. No serious adverse effects from treatment were encountered by patients during this study. Gastrointestinal complaints occurred in several patients, but they were generally mild and did not lead to the discontinuation of the regimen in any cases. Nausea or vomiting occurred in 21 (21%) and diarrhea in 19 (19%) of 101 patients, but no significant differences in these symptoms occurred between antibiotic treatment groups. In the majority of these cases, the nausea was mild, without vomiting. In no case was it necessary to discontinue antibiotic treatment because of persistent symptoms. In two patients in the cefoxitin-doxycycline group and in one in the clindamycin-tobramycin group a mild rash developed. Blood urea nitrogen and serum creatinine were tested before and after completion of therapy in 47 patients, and all test results were within the normal range both before and after therapy. There were no differences between treatment groups in the increase of blood urea nitrogen or creatinine within the normal range. Serum glutamic oxaloacetic transaminase levels were tested before and after therapy in 34 patients. Abnormal serum glutamic oxaloacetic transaminase elevations occurred in eight patients, five of

whom had abnormal serum glutamic oxaloacetic transaminase values before treatment; no difference occurred in this value between antibiotic treatment groups.

Comment

N. gonorrhoeae has been linked with acute pelvic inflammatory disease since the early 1900's. Although the recovery of *N. gonorrhoeae* varies widely depending on the population, the microorganism is usually isolated from 30% to 50% of patients with pelvic inflammatory disease in the United States.[1, 2, 4, 20, 21] *C. trachomatis* has only recently been recognized to cause pelvic inflammatory disease; usually *C. trachomatis* is isolated in 25% to 50% of women with pelvic inflammatory disease.[3, 7, 22-28] *C. trachomatis* has been particularly associated with long-term sequelae of pelvic inflammatory disease, such as infertility and ectopic pregnancy.[28, 29] In this report *N. gonorrhoeae* was isolated from one half of the patients with acute pelvic inflammatory disease, *C. trachomatis* was isolated from one third of these patients, and either *N. gonorrhoeae* or *C. trachomatis* was isolated from more than two-thirds of these patients. Usually it is not possible to determine which of these bacteria are present at the time of antibiotic initiation. Because these microorganisms are isolated frequently, antibiotic regimens used for the treatment of pelvic inflammatory disease should be effective against both *N. gonorrhoeae* and *C. trachomatis*.

This report represents a multicenter direct comparison of the first two combination antimicrobial regimens recommended by the Centers for Disease Control for the treatment of hospitalized patients with pelvic inflammatory disease.[9-11] These regimens were recommended because they treat *N. gonorrhoeae*, and it was anticipated that they would adequately treat *C. trachomatis*. In fact, both cefoxitin-doxycycline and clindamycin-tobramicin appeared to effectively eradicate *C. trachomatis* from our patients. Doxycycline is more active than clindamycin against *C. trachomatis* in vitro, but the multidose administration of clindamycin at the dose used in this report also appears to be effective. Additionally, these regimens have good activity against the facultative and anaerobic microorganisms that are associated with pelvic inflammatory disease, although it was not possible to obtain posttherapy tubal cultures from our patients.

The antimicrobial regimens used in this study are not those traditionally chosen to treat patients with acute pelvic inflammatory disease. The majority of patients with pelvic inflammatory disease have continued to be treated as outpatients with a single antibiotic,[6] and many of the commonly selected oral antibiotics do not effectively inhibit *C. trachomatis*. In addition, the most frequently used inpatient therapies also have consisted of single antibiotics, the most common of which are cephalosporins and aminopenicillins.[6] While these single-agent regimens would be expected to eliminate *N. gonorrhoeae*, cephalosporins are particularly ineffective against *C. trachomatis*. In the best available example, *C. trachomatis* was reisolated from 12 of 13 patients with pelvic inflammatory disease who were treated only with cephalosporins.[7] Tetracyline has good activity against *C. trachomatis*, but it is disturbing that the use of tetracycline for hospitalized patients has actually decreased from 30% in 1966 to 20% in 1983,[6] during a time in which the importance of *C. trachomatis* in pelvic inflammatory disease was increasingly recognized.[5, 23, 25, 26]

The microbiologic makeup of acute pelvic inflammatory disease consists of a wide variety of facultative and anaerobic microorganisms, including *N. gonorrhoeae* and *C. trachomatis*. In this study we recovered *N. gonorrhoeae* from 53% of the patients evaluated and *C. trachomatis* from 31%. The recovery rates of these microorganisms were less (43% and 22%, respectively) from the endometrium. Thirty-seven percent of the 43 patients who had fallopian tube cultures had *N. gonorrhoeae*, and 12% of these patients had *C. trachomatis*.

The organisms were similar to those recovered from the upper genital tract of women with acute pelvic inflammatory disease in studies from Scandinavia and the United States.[1-4] *C. trachomatis* was the most common individual organism recovered from the upper genital tract of women with pelvic inflammatory disease in Scandinavia; however, Heinonen et al.[30] and Paavonen et al.[31] noted that anaerobic and/or facultative bacteria were recovered from 68% (17/25) and 69% (24/35) of their patients. In the United States, Wasserheit et al.[26] and Sweet[28] have reported recovery of anaerobic and/or facultative bacteria from the upper genital tract in 44% (11/23) and 69% (115/188) of patients with acute pelvic inflammatory disease. Interestingly, many of these anaerobic and facultative bacteria are the microorganisms that are associated with bacterial vaginosis.[32] Eschenbach[33] initially suggested that bacterial vaginosis might be a precursor for the development of pelvic inflammatory disease as the result of anaerobic and/or facultative bacteria. Recently, Paavonen et al.[31] demonstrated that such an association between bacterial vaginosis and pelvic inflammatory disease does exist and reported that bacterial vaginosis was present in 9 (29%) of 31 women with acute pelvic inflammatory disease, whereas it was not present in any of the 14 control patients. Thus regimens used to treat endometritis and salpingitis also should adequately treat these microorganisms.

The endometrial isolation of *M. hominis* was not appreciably reduced by the cefoxitin-doxycycline regimen, although *M. hominis* was eliminated by

clindamycin-tobramycin. The failure of doxycycline to eradicate *M. hominis* is probably related to the increasing prevalence of plasmid-mediated, tetracycline-resistant *M. hominis* strains.[34] If the goal of treatment is to render the upper genital tract sterile, then with respect to *M. hominis*, the cefoxitin-doxycycline regimen is not effective. However, women with *M. hominis* did not have symptoms, and ultimately the importance of *M. hominis* in pelvic inflammatory disease is unclear.[28] Although *M. hominis* can be recovered from the fallopian tubes of a small number of women with pelvic inflammatory disease,[1, 2, 35] the microorganism does not appear to ascend intracanalicularly from the cervix to infect the human fallopian tube.[34] Moreover, in vitro studies have failed to demonstrate that *M. hominis* produces adverse tissue destruction of the tubal epithelium,[36] in contradistinction to the tubal epithelium destruction demonstrated in tubal explants with *N. gonorrhoeae*[37] and in animal models for *C. trachomatis*[38] and *B. fragilis*.[39]

In previous studies up to one third of patients with a clinical diagnosis of pelvic inflammatory disease did not have salpingitis confirmed by laparoscopy.[14, 24-26] Inclusion of patients with no disease or with other conditions in antibiotic trials may alter the apparent clinical response. In this study patients had either laparoscopy, endometrial biopsy, or a constellation of clinical findings that reduced the number of those with no disease or with other conditions to a minimum. The clinical response of patients given either treatment regimen was judged to be satisfactory in 98% of patients with uncomplicated acute pelvic inflammatory disease. Too few patients were studied to detect a true difference (β-error) between drug regimens, if in fact a difference exists. In trials with other antibiotics, high degrees of efficacy judged by clinical parameters also have been observed,[5, 8, 21, 26] but patients with *C. trachomatis* were not analyzed as a separate group. In this trial the initial clinical response was high, not only for patients with *N. gonorrhoeae* but also for those with *C. trachomatis*. The clinical response appears to be better for patients with uncomplicated pelvic inflammatory disease than for patients with tuboovarian abscesses, but >80% of patients with tuboovarian abscesses showed a favorable clinical response to the antibiotic regimens used in this study.

The tenderness score was used in an attempt to evaluate more subtle response differences than was possible with an overall clinical response. Posttreatment tenderness scores were similar for patients treated with either drug regimen. However, reduction of the tenderness occurred slowly, and only two thirds of the patients had >70% reduction of tenderness at the time of hospital discharge. Some of these patients had a subsequent increase in tenderness. The tenderness score was used in an attempt to refine the clinical response; however, this assessment is still a crude measure of the response of infection to antibiotic therapy. In addition, the tenderness score has not been correlated with direct laparoscopic observations of the pelvis to determine whether persistent tenderness indicates a poor response, as indicated by persistent pelvic infection or by anatomic pelvic abnormalities, or whether persistent tenderness in a subset of patients is unassociated with objective evidence of disease. We support the attempts to develop better criteria to assess outcome.[40] Considerably more study of short-term (early) and long-term (late) outcome is needed. Short-term effects of therapy on the fallopian tubes can be evaluated directly by laparoscopy or by hysterosalpingography that is performed several months after therapy has concluded, although the approach is expensive. Long-term outcomes can be evaluated by assessing persistent pain, infertility rates, ectopic pregnancy rates, and need for surgical intervention of chronic pelvic pain.

Cost comparison between the two regimens includes not only the cost of the antibiotics but also charges for mixing and preparation and for administering each dose. We noted dramatic differences in the costs of these various services between the two hospitals. While the drug costs were higher in the cefoxitin-doxycycline group, higher total hospital costs were noted in the clindamycin-tobramycin group in spite of a similar number of hospitalization days between the groups. Thus meaningful cost comparisons between the two regimens is not possible. The current recommendation of the Centers for Disease Control to use gentamicin and dosing of clindamycin every 8 hours is probably designed to reduce the cost of this regimen.

In summary, the regimens recommended by the Centers for Disease Control for the treatment of hospitalized patients with pelvic inflammatory disease (either cefoxitin in combination with doxycycline or clindamycin in combination with an aminoglycoside) were highly and equally effective. No serious or significant side effects or toxicity was associated with either regimen. However, there are both short-term and long-term assessments of the treatment of acute pelvic inflammatory disease. The short-term assessment is based on immediate clinical response to treatment, reduction of hospitalization time, and prevention of relapse. On the other hand, the long-term goal, which may be even more important, is to preserve fallopian tube function, that is, to prevent tubal factor infertility and/or ectopic pregnancy.

Westrom,[41] in a cohort study in Sweden, demonstrated that the overall infertility rate was 21% after one or more (laparoscopically) documented episodes of acute pelvic inflammatory disease. He noted a direct linear relationship between the number of episodes of

infection and the infertility rate, which ranged from 11% for a single episode to >50% in women with three or more episodes. In addition, he reported a sixfold increase in tubal ectopic pregnancy among women with acute pelvic inflammatory disease. No such large-scale study to assess the long-term sequelae of acute pelvic inflammatory disease has been reported in the United States.[42] However, Brunham[43] in Canada recently described poor fertility prognosis in 7 of 23 laparoscopically confirmed pelvic inflammatory disease cases in which pregnancy attempted. All patients with adverse reproductive outcomes had either *C. trachomatis* infection or abscess formation, which is predominantly associated with anaerobic bacteria.

Our results support the use of broad-spectrum combination therapy for the treatment of acute pelvic inflammatory disease, although improved methods of measuring both short-term and long-term response to therapy are needed. Future studies should determine the long-term sequelae that develop after various inpatient versus outpatient treatment regimens. Patients must undergo long-term follow-up to determine their ultimate response to therapy and the effect of various treatment regimens on future infertility, ectopic pregnancy, and recurrence of pelvic inflammatory disease.

Finally, this study clearly demonstrates the effectiveness of high-dose clindamycin for the treatment of *C. trachomatis* infection in the setting of acute pelvic inflammatory disease. In none of the 20 cases with chlamydial infection in the clindamycin group was the organism recovered ≥3 weeks after treatment. This finding, plus the previous efficacy of clindamycin for treatment of chlamydial pelvic inflammatory disease as noted by Wasserheit et al.[26] raises serious questions about the most recent recommendations from the Centers for Disease Control for the treatment of hospitalized patients with acute pelvic inflammatory disease. In these recommendations follow-up treatment with doxycycline is suggested for patients initially treated with the clindamycin and gentamicin regimen.[11] It seems clear that clindamycin in high doses is adequate therapy for *C. trachomatis* infection in women.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Meconium-stained amniotic fluid: A risk factor for microbial invasion of the amniotic cavity

Roberto Romero, MD, Shuichi Hanaoka, MD, Moshe Mazor, MD, Apostolos P. Athanassiadis, MD, Robert Callahan, BS, Yu Chiung Hsu, MD, Cecilia Avila, MD, Jose Nores, MD, and Carlos Jimenez, MD

New Haven, Connecticut

The purpose of this study was to determine whether meconium-stained amniotic fluid is a marker for microbial invasion of the amniotic cavity. Amniocentesis was performed on 707 patients presenting with preterm labor and intact membranes. Meconium-stained amniotic fluid was present in 4.2% (30/707) of patients with preterm labor. The prevalence of positive amniotic fluid cultures was significantly higher in women with meconium-stained amniotic fluid than in women with clear fluid (33% [10/30] vs 11% [75/677]; $p = 0.001$; odds ratio = 4.01; 95% confidence interval = 1.6 to 9.4). Patients with meconium-stained amniotic fluid were also more likely to have failed tocolysis and delivered a preterm neonate more frequently than patients with clear fluid (83% [25/30] vs 38% (258/677); $p = 0.0001$; odds ratio = 8.1; 95% confidence interval = 2.9 to 24.4). We conclude that meconium-stained amniotic fluid is a risk factor for microbial invasion of the amniotic cavity and preterm delivery in women with preterm labor and intact membranes. (Am J Obstet Gynecol 1991;164:859-62.)

Key words: Preterm labor, meconium, amniotic fluid, parturition, chorioamnionitis, intraamniotic infection, tocolysis, prematurity, discolored amniotic fluid, *Listeria monocytogenes*

Meconium-stained amniotic fluid is traditionally considered a sign of fetal hypoxia (reviewed in detail in reference 1). However, fetal acidosis is present in only a small fraction of cases with meconium-stained amniotic fluid, and the cause of and mechanisms responsible for meconium passage in the remainder of cases remain undetermined.[1] Intraamniotic infection with *Listeria monocytogenes* is associated with meconium-stained amniotic fluid.[2] Although the mechanism underlying this phenomenon is unknown, ingestion of infected amniotic fluid may lead to fetal enteritis and passage of meconium. Therefore the possibility must be considered that meconium-stained amniotic fluid may be a marker for microbial invasion of the amniotic cavity.

To address this question, we constructed a study of women presenting with preterm labor and intact membranes. This population was chosen because amniocentesis is routinely performed to screen for microbial invasion of the amniotic cavity.

Material and methods

Patient population. Patients admitted to Yale–New Haven Hospital with the diagnosis of preterm labor and intact membranes from April 1, 1985, to March 31, 1989, underwent amniocentesis for evaluation of the microbiologic status of the amniotic fluid. Immediately after amniocentesis, the color of amniotic fluid was recorded by the operator.

Preterm labor was defined as the presence of regular uterine contractions with a frequency of at least two every 10 minutes associated with cervical change. Nitrazine, pooling, and ferning tests were performed in every case during a sterile speculum examination to exclude leakage of amniotic fluid into the vagina. Ritodrine, terbutaline, or magnesium sulfate was administered intravenously for tocolysis. Failure of tocolysis was diagnosed when cervical dilatation progressed beyond 3 cm and/or delivery occurred.

Microbiologic culture technique. Amniotic fluid was transported to the laboratory in a capped plastic syringe immediately after collection. These conditions precluded air contact with the specimen. Plating occurred

Table I. Microbial isolates from patients with meconium-stained amniotic fluid and positive cultures

Microorganism	*Incidence*	*Colony count (CFU/ml)*
Mixed anaerobic bacteria	4	10^2, 10^5, 10^2, 10^4
Ureaplasma urealyticum	3	NA
Listeria monocytogenes	2	$>10^5$, NA
Mycoplasma hominis	1	NA
Streptococcus viridans	1	$>10^5$
Peptococcus asaccharolyticus	1	1600
Bacteroides fragilis	1	$>10^5$

within 30 minutes of collection in most cases. Amniotic fluid was cultured for aerobic and anaerobic bacteria, as well as for *Mycoplasma sp.* (*Mycoplasma hominis* and *Ureaplasma urealyticum*), using methods previously described.[3] An intraamniotic infection was defined as the presence of a positive amniotic fluid culture for microorganisms.

Statistical analysis. Analysis of the data was conducted with a χ^2 test (True Epistat, Epistat Services, Richardson, Tex.).

Results

During the study period, there were 707 patients with the diagnosis of preterm labor and intact membranes whose amniocentesis reports contained information about the color of the amniotic fluid. Meconium-stained amniotic fluid was detected in 4.2% of cases (30/707). The prevalence of positive amniotic fluid cultures for microorganisms was higher in women with meconium-stained fluid than in women with clear amniotic fluid (33% [10/30] vs 11% [75/677]; $p = 0.001$; odds ratio = 4.01; 95% confidence interval = 1.6 to 9.4).

Table I displays the microbiologic findings in the 10 cases of patients with meconium-stained amniotic fluid. It is noteworthy that there were two cases with *Listeria monocytogenes* intraamniotic infection. The most prevalent microorganism was *Ureaplasma urealyticum* ($n = 3$).

There were no differences in gestational age on admission, interval to delivery, and birth weight between women with meconium and positive cultures and those with meconium and negative cultures (Table II).

Women with meconium-stained amniotic fluid were more likely to have failure of tocolysis and be delivered of a preterm neonate than women without meconium (83% [25/30] vs 38% [258/677]; $p = 0.0001$; odds ratio = 8.1; 95% confidence interval = 2.9 to 24.4).

Comment

Pathologic studies have documented an association between meconium-stained amniotic fluid and the presence of inflammatory lesions of the placenta and membranes.[4] These lesions were originally attributed to the irritant effect of meconium. Subsequent studies demonstrated that injection of sterile meconium into animals failed to induce an inflammatory tissue response.[5] An alternative explanation for these pathologic findings is that meconium is passed when there is microbial invasion of the amniotic cavity. This tenet is consistent with previous observations in which infants born to mothers with meconium-stained fluid had a higher incidence of perinatal infections.[6] Our data support an association between meconium-stained amniotic fluid and intraamniotic infection in the context of preterm labor.

Three general possibilities might be considered to explain our findings: (1) Swallowed bacteria may induce meconium passage; (2) meconium may impair the antibacterial properties of amniotic fluid and promote bacterial growth; (3) an intrauterine ascending infection may lead to decidual bleeding and the appearance of meconium-like amniotic fluid.[7]

There is a striking association between intraamniotic infection with *Listeria monocytogenes* and meconium-stained amniotic fluid.[2] The mechanism postulated to explain this phenomenon is that ingestion of infected amniotic fluid leads to a fetal enteritis and subsequent meconium passage. It is unclear why some intraamniotic infections are associated with meconium-stained fluid whereas others are not. The type and virulence of the organism, inoculum size, and gestational age of the fetus may be important factors. For example, *Listeria monocytogenes* is a particularly virulent microorganism, whose port of entry is the gastrointestinal tract. The clinical picture of listeriosis often includes gastroenteritis with diarrhea. A similar mechanism may be operative in utero. In our series the two cases with *Listeria monocytogenes* intraamniotic infection had meconium-stained fluid. Other types of organisms using the gastrointestinal tract as the port of entry (i.e., enteroviruses) also may cause in utero meconium passage (Romero R. Unpublished observations).

In this series, it is noteworthy that, except for *Listeria*, the microbial isolates of women with meconium-stained amniotic fluid were not different from those recovered from women with intraamniotic infection and clear am-

niotic fluid. We were unable to document a relationship between inoculum size or gestational age and the presence of meconium-stained amniotic fluid. It is not possible to determine whether virulence of a particular strain may play a role.

The increased prevalence of microbial invasion of the amniotic cavity in women with meconium-stained amniotic fluid may be related to alteration of the host-defense mechanism due to the presence of meconium. Amniotic fluid has physiologic antimicrobial properties which are impaired by the addition of meconium.[8, 9] Recently, it has been proposed that the mechanism by which meconium enhances bacterial growth is the alteration of the zinc-to-phosphorus ratio.[10]

Up to this point, our discussion has assumed that the identification of discolored amniotic fluid as meconium stained is accurate. However, the presence of green-stained amniotic fluid may be the result of contamination of amniotic fluid with hemoglobin and its catabolic products. This observation has been made in mid-trimester amniotic fluid and with in vitro experiments.[11] We propose that an ascending intrauterine infection may cause deciduitis and hemorrhage. Passage of hemoglobin and its metabolic by-products into the amniotic fluid may then lead to brown- or green-colored fluid. This postulate is consistent with the observations of Cassell et al.[12] who reported the recovery of *Mycoplasma hominis* and *Ureaplasma urealyticum* in 12% of samples with discolored, second-trimester amniotic fluid.

The prevalence of meconium-stained/discolored amniotic fluid in this study was 4.2%, which is similar to the 5% reported by Ostrea and Naqvi[13] in patients with a gestational age of <38 weeks. Although the frequency of meconium-stained amniotic fluid varies among different reports, there is general agreement that the prevalence is higher in term and postterm pregnancies than in preterm gestations. This finding has been attributed to maturation of the mechanisms responsible for meconium passage.[14]

Another finding of our study is that patients with meconium-stained/discolored amniotic fluid were more likely to fail tocolysis and to deliver prematurely than women with clear fluid. This association remained highly significant even after women with intraamniotic infections were removed from the data set (75% [15/20] vs 30.2% [183/602]; $p = 0.00007$; odds ratio = 6.8; 95% confidence interval = 2.3 to 21.9). In this setting the presence of meconium-stained/discolored amniotic fluid may be a clinical marker for pathologic processes associated with preterm labor (i.e., fetal distress, abruptio placentae, etc.).

The clinical significance of this report is the identification of meconium-stained/discolored amniotic fluid as a risk factor for microbial invasion of the amniotic cavity and preterm delivery. This study has focused on the preterm gestation. Given the high prevalence of unexplained meconium passage in term and postterm gestations and the seriousness of its sequelae, the possible association between intraamniotic infection and meconium-stained fluid at term must be examined.

We gratefully acknowledge the assistance of Carol A. Brekus, MSN, CNM, and Valerie W. Kraemer, MFA.

Mild fetal lateral cerebral ventriculomegaly: Clinical course and outcome

Bryann Bromley, MD, Fredric D. Frigoletto, Jr., MD, and Beryl R. Benacerraf, MD
Boston, Massachusetts

The neonatal, pathologic outcome and karyotypic abnormalities are reported for 44 fetuses with mild ventriculomegaly diagnosed antenatally. Seventeen of these 44 fetuses (39%) had other ultrasonographic defects, and five (12%) had abnormal karyotypes. Five pregnancies were electively aborted and three other fetuses died in the neonatal period. Twenty-six (72%) of the remaining 36 live-born neonates are developmentally and clinically normal at 3 to 18 months of age. Twenty-one of these 26 had isolated mild ventriculomegaly as the only ultrasonographic finding. The other 10 live-born infants are developmentally impaired, and five of these 10 had mild ventriculomegaly as the only prenatal ultrasonographic abnormality. In conclusion, these data show that fetuses with mild ventriculomegaly have a lower incidence of associated anomalies and a better outcome than fetuses with more severe ventricular dilatation, as reported in the literature. The majority of fetuses with mild ventriculomegaly as an isolated finding and a normal karyotype are developing normally. (Am J Obstet Gynecol 1991;164:863-7.)

Key words: Ventriculomegaly, karotype, anomaly

Congenital ventriculomegaly is a serious malformation of the central nervous system occurring in one per 1000 fetuses. It is often associated with a poor prognosis.[1] Prenatal ultrasonography accurately detects fetal central nervous system anomalies, including ventriculomegaly, permitting counseling of expectant parents concerning predicted outcomes.[2-6] Estimation of ventricular size has become an important part of the prenatal ultrasonogram in the assessment of brain development. The atria of the normal lateral vetricles remain relatively constant in size throughout gestation, with a mean diameter of 7.6 ± 0.6 mm.[7, 8] Ventriculomegaly is suspected when the atrial diameter reaches 10 mm.[7, 3] Although the outcome of severe ventriculomegaly is poor and has been extensively studied, the natural history and significance of mild or borderline ventriculomegaly is unknown. We report the associated congenital and karyotypic abnormalities and clinical outcome in 44 patients with mild ventriculomegaly (atrial measurement 10 to 12 mm) diagnosed antenatally with ultrasonography.

Material and methods

Mild ventriculomegaly was considered present when the axial ultrasonogram of the brain demonstrated an atrial diameter of the lateral ventricle between 10 and 12 mm. Forty-nine consecutive fetuses between 16 and 37 weeks' gestation, scanned between February 1987 and May 1990 and delivered by June 1, 1990, met this criterion (Fig. 1). Clinical follow-up was available in 44 patients by review of the pediatric record, consultation with the pediatrician, and discussion with the parents. Five patients were unavailable for follow-up or had inadequate or incomplete information and were excluded from the study.

Each scan was reviewed retrospectively; an image of the atrium of the lateral ventricle was available in each case. The atrium of the lateral ventricle had been photographed prospectively as part of the scan and was retrospectively measured and analyzed in each case. If the lateral ventricular atrium measured between 10 and 12 mm, the patient was included in the study regardless of indication for the scan. Other findings tabulated included the assessment of anmiotic fluid volume and evidence of other congenital malformations at the time of the original ultrasonogram. Each scan was done with an Acuson 128 variable-focus 3.5 MHz sector transducer; each patient was scanned by a single sonologist. Clinical circumstance dictated interval of ultrasonographic follow-up examinations.

Results

The ultrasonographic diagnosis of mild ventriculomegaly was made in 49 consecutive fetuses between the gestational ages of 16 and 37 weeks (Fig. 2). Forty-four patients had adequate follow-up of their neonates between 3 and 18 months of age. All patients consecutively noted to have mild ventriculomegaly (atrium of the lateral ventricle between 10 and 12 mm, Fig. 1)

were included in the study, regardless of indication for the ultrasonogram. Mild ventriculomegaly was identified ultrasonographically in 21 patients at low risk for having central nervous system abnormalities. There were 13 patients who were referred to our facility because of suspected ventriculomegaly on a level I ultrasonogram, two others because of an abnormal α-fetoprotein value, and eight more who were believed to have an abnormality not related to the central nervous system (Table I).

Seventeen of the 44 fetuses (39%) with mild ventriculomegaly had other abnormalities detected ultrasonographically. Six of these had other central nervous system anomalies and 11 had non–central nervous system defects (Table II).

Hydrops	1
Duodenal atresia	1

*Several fetuses appear in more than one category.

Twelve patients underwent cytogenetic studies at the discretion of the referring obstetrician because of advanced maternal age, abnormal α-fetoprotein level, or multiple fetal anomalies. Five of these amniocenteses revealed an abnormal karyotype: Three fetuses had trisomy 21, one had trisomy 18, and one had a 7p- karyotype. All five fetuses with karyotypic abnormalities had other abnormal ultrasonographic findings, although the patient with the 7p- karyotype had coarctation of the aorta, which was difficult to detect ultrasonographically. The fetuses with trisomy 21 had hydrops, duodenal atresia, cardiac defects, and intrauterine growth retardation. Although not all fetuses actually had karyotyping done, those who did not undergo amniocentesis did not show any clinical suggestion of aneuploidy after birth. Only one patient who underwent pregnancy termination for neural tube defect did not have karyotypic information either in utero or at termination (Table III). The overall incidence of abnormal karyotype in our study therefore was five of 43 (12%).

Of our 44 patients, 32 had follow-up scans in utero, with normalization of the lateral ventricular measurement in five. Four of these five neonates exhibited normal development at 6 to 15 months of life. The other infant had congenital glaucoma. These five fetuses were initially diagnosed as having mild ventriculomegaly (atrium, 10 to 12 mm) between 27 to 32 weeks' gestation, and had normalized (atrium, ≤9 mm) by 33 to 37 weeks.

Twenty-three patients had postnatal radiologic or pathologic follow-up revealing abnormal intracranial findings in 11 patients. These follow-up scans were done at the discretion of individual pediatricians. None of the neonates required shunting.

Five pregnancies ended in elective abortion and three

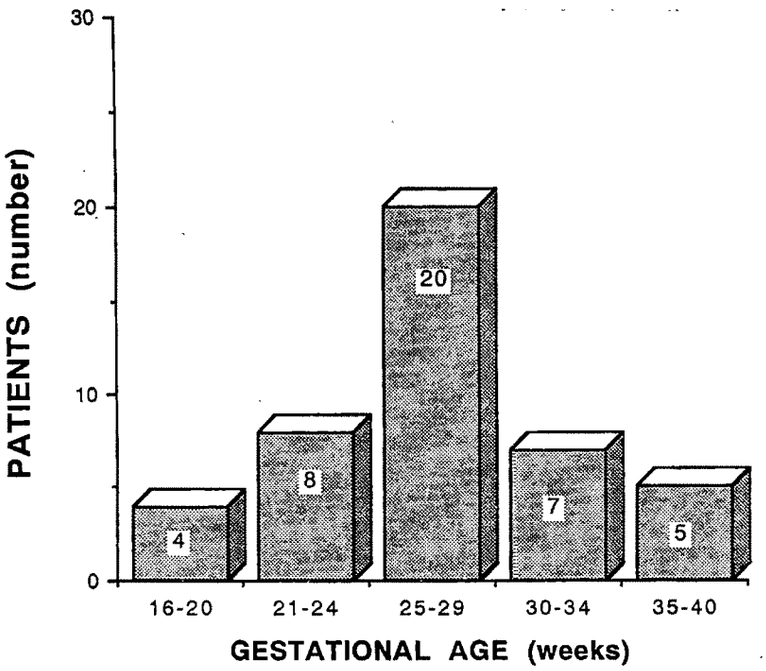

Fig. 2. Graph showing gestational age of fetuses with mild ventriculomegaly.

Table III. Fetal deaths (total 8 patients)

	Karyotype
Elective abortion (5 patients)	
Isolated ventriculomegaly	Normal amniocentesis
Neural tube defect (2 patients)	One with normal amniocentesis
Abnormal distal limbs	Normal amniocentesis
Trisomy 21	Trisomy 21
Fetal or neonatal death (3 patients)	
Heterotaxy syndrome with heart defect	Normal karyotype
Trisomy 21 with hydrops	Trisomy 21
Trisomy 18 with multiple anomalies	Trisomy 18

had intrauterine fetal death or neonatal death. The associated pathologic conditions of these eight losses are shown in Table III.

Developmental information was available in all 36 pregnancies with living children by reports from pediatricians or pediatric neurologists in the majority of cases, as well as by interviews with parents (Fig. 3). Twenty-six neonates were reported to be clinically and developmentally normal at 3 to 18 months of age. Ten patients (28%) were clinically or developmentally impaired, as shown in Table IV. These 10 infants were all considered impaired by their pediatricians or neurologists using standard pediatric assessment.

Isolated ventriculomegaly with no other congenital defect was noted in 27 of the total 44 patients, and 21 of these are developing normally. Five of the 27 with isolated ventriculomegaly are handicapped (hearing impaired, congenital glaucoma, congenital seizures, and two with mild delay in motor development). One underwent pregnancy termination. From a different viewpoint, 26 of the total 44 neonates are developing normally; of these, 21 had isolated ventriculomegaly. The five neonates developing normally with other ultrasonographic findings included one with agenesis of the corpus callosum, one with an omphalocele, one with a cleft lip and palate, and two with transient ascites. From yet another perspective, five of the 10 fetuses with abnormal developmental outcomes had no other ultrasonographic defects and five had other congenital abnormalities, including one each with a neural tube defect, subarachnoid cysts, and clubbed feet and two with congenital heart defects (both of whom had abnormal karyotypes).

There were 13 of 44 pregnancies (30%) that were complicated by polyhydramnios, seven of which had other ultrasonographically identified defects. Three of

these 7 fetuses died and one other is developing abnormally. The other nine neonates are developing normally.

In conclusion, of the total 44 patients with clinical follow-up, 26 of 44 (59%) of the infants were developing normally, 12% had abnormal karyotypes, and 18% were either electively aborted or stillborn. Of the 36 live births, 26 of 36, or 72%, resulted in developmentally normal neonates.

Comment

Fetal intracranial ventricular enlargement has been associated with a poor prognosis, regardless of cause.[2-6] Previous series have shown that the majority of fetuses with significant ventriculomegaly have associated major abnormalities and an unfavorable outcome. Vintzileos et al.[2] reported associated abnormalities in 70% of fetuses with ventriculomegaly. Only 45% of the neonates in his study were alive, but more than half of these were developmentally impaired. Chervenak et al.[3] described 53 fetuses with enlarged ventricles, 83% of whom had other developmental abnormalities, with only 28% survival. Nyberg et al.[4] also reported that a majority of fetuses with ventriculomegaly had other congenital abnormalities; this was associated with a universally fatal outcome in their series. Pretorius et al.[5] found the prognosis of fetuses with enlarged intracranial ventricles to be poor, with only 15% survival at 13 months of age and half of those developing abnormally. This is in agreement with the work of Chervenak et al.,[3] which showed that in a series of fetuses with ventriculomegaly there were associated abnormalities in 85% of cases.

Mahony et al.[9] reported on 20 fetuses with mild dilatation of the lateral ventricles. In their study 40% of fetuses with ventriculomegaly had a normal outcome, 40% of fetuses died, and 20% had an uncertain prognosis. Their criteria for ventriculomegaly was based on the distance between the medial aspect of the lateral ventricular atrium and medial surface of the choroid plexus, which is not a well-established landmark for describing hydrocephalus. In their patients the atrial diameter was between 9 and 15 mm, which is a wider span than reported here. We considered an atrial measurement of >12 mm not to represent mild ventriculomegaly.

A recent study by Goldstein et al.[10] describing 55 cases of mild ventriculomegaly showed that isolated mild ventricular dilatation had a better prognosis than nonisolated ventriculomegaly. However, they included atrial measurements up to 15 mm, which we believe is more than mild ventricular dilatation. Also, their mortality figures (40 of 55 fetuses, or 73%) were much higher than ours, presumably because many patients underwent termination of pregnancy (30 of 55 patients).

A dilemma exists when ventriculomegaly is only mild or when the ventricles are borderline in size. Although it is not a challenge to diagnose severe ventriculomegaly in utero, it may be difficult for the ultrasonologist to decide whether minimal ventriculomegaly or borderline atrial enlargement represents a true abnormality. The prenatal diagnosis of ventriculomegaly has devastating implications in terms of fetal survival and infant development, which may alter the management of the pregnancy, thereby influencing outcome. Cardoza

et al.[8] reported that the mean diameter of the normal atrium of the lateral ventricles is constant throughout gestation and measures 7.6 ± 0.6 mm. These authors considered an atrial width >10 mm to be abnormal. Although it is clear that gross ventriculomegaly indicates a true abnormality, the atrial ventricular size between 10 and 12 mm is a gray area and the outcome of affected fetuses has not previously been investigated systematically. It is difficult to know how to counsel a patient whose fetus has ventricular measurements in this borderline area; for example, there have been two case reports of resolution of mild ventriculomegaly, which may have represented fetuses in this intermediate zone.[11, 12]

Our data show that fetuses who have lateral ventricular measurements betweeen 10 and 12 mm have a better outcome than those reported in the literature who have obvious ventricular enlargement. In our study 26 of 44 (59%) of all the neonates are developing normally, and of those with isolated ventriculomegaly whose pregnancy was not electively terminated, 21 of 26 (80%) resulted in normal neonates, a much better outcome than in previously reported studies of ventriculomegaly. Only 17 (39%) of the total of 44 fetuses had other anomalies identified, which is a lower rate of associated anomalies than reported with more severe ventricular enlargement.[3-6]

However, not all fetuses with isolated ventriculomegaly had good outcomes. Of the 10 fetuses with abnormal development, half had isolated ventriculomegaly and the other half had other congenital defects. Conversely, although the majority of the 26 fetuses developing normally had isolated ventriculomegaly, five of these 26 clinically normal fetuses had other congenital defects demonstrated ultrasonographically (one omphalocele, one agenesis of the corpus callosum, one facial cleft, and two transient ascites).

A limitation of this study was that the neurologic examination was done by individual pediatricians or pediatric neurologists and was not standardized. However, the clinical data from each of the 10 children considered impaired were obtained directly from the pediatrician or pediatric neurologist. All other neonates (considered normal) had normal results of pediatric examination and frequently normal head ultrasonograms.

In summary, although 80% of fetuses with isolated ventriculomegaly are developing normally, 50% of those with other congenital defects showed developmental impairment, suggesting that the detection of additional structural defects worsens the prognosis.

Five (12%) of 43 had abnormal karyotypes, indicating that cytogenetic studies should be considered when mild ventriculomegaly is detected ultrasonographically, particularly if other abnormalities are visualized. Although actual karyotypes were available on 12 patients, all those with abnormal karyotypes had other ultrasonographic findings besides ventriculomegaly, putting them at higher risk of aneuploidy than those with isolated ventricular dilatation. Furthermore, there was no clinical evidence of aneuploidy among the remaining 31 infants (one additional patient with a fetus having a neural tube defect aborted with inadequate information regarding chromosomes). It is of note that two of the fetuses with abnormal chromosome complements in our study had subtle cardiac anomalies that might not always be recognized ultrasonographically unless formal echocardiography is done.

In conclusion, there appears to be a subset of fetuses with mild ventriculomegaly who may have fewer associated anomalies and a better prognosis than those more severely affected. Although the lateral ventricular atrial width of ≥10 mm is definitely abnormal, the majority of fetuses with this measurement as an isolated finding in the setting of a normal karyotype are developing normally. When mild ventriculomegaly is detected ultrasonographically, karyotypic studies and follow-up scans are recommended. It is clear that further studies will be necessary to study long-term development of these children. However, the presence of mild ventriculomegaly seems to be associated with a more optimistic outcome than moderate or severe ventricular enlargement.

Hospital setting and fetal death during labor among women at low risk

Leah L. Albers, DrPH,[a] and David A. Savitz, PhD[b]
Chapel Hill, North Carolina

Intrapartum fetal death in low-risk women at term is a rare obstetric outcome. This is difficult to study because few data sets contain an adequate number of cases for meaningful analysis. This study used data from the 1980 National Natality Survey and National Fetal Mortality Survey, merged with an American Hospital Association annual survey for the same year, to determine whether the frequency of intrapartum fetal death in low-risk women varied by the hospital setting for birth. Stratified analysis was used to assess the relation of level of hospital for delivery with intrapartum fetal death, with control for potential confounding factors. As the level of available perinatal technology decreased, the frequency of intrapartum fetal death increased (odds ratio, 2.0 for Level II and 3.3 for Level I, as compared with Level III hospitals). Even when early neonatal deaths were considered, perinatal mortality remained lowest at Level III facilities (odds ratio, 1.6 for Level II and 2.7 for Level I, as compared with Level III hospitals). The components of intrapartum surveillance that are most effective in the reduction of perinatal mortality have not been identified. (AM J OBSTET GYNECOL 1991;164:868-73.)

Key words: Obstetrics, hospital level, intrapartum fetal death

Avoidance of fetal death remains an important concern of perinatal health professionals. Since the late 1970s, perinatal mortality has been made up of proportionately more fetal than neonatal deaths.[1] The risk of fetal death is known to decline as gestation advances,[2] and fetal death occurs with increased frequency at the extremes of reproductive age,[1,2] in women of high parity,[3] those with medical problems,[2,4] smokers,[5] and the socially disadvantaged.[6]

Most fetal deaths occur during the antepartum period, before the onset of labor. Large vital records series have shown that in pregnancies beyond 24 weeks' gestation, 12.8% of fetal deaths occur during labor.[3] Intrapartum fetal death is thought to be sensitive to the level of obstetric care,[7] with the frequency declining as the technical sophistication of the hospital for delivery is increased. If lethal anomalies are excluded, intrapartum fetal death is presumed to be largely caused by maternal or placental factors that may be amenable to medical intervention.[4] This opportunity for successful intervention is less apparent for fetal deaths that occur before labor begins.

Women at low risk constitute a large group that uses considerable health resources, particularly given essentially universal hospitalization for birth in the United States. Low-risk women are delivered in all hospital settings, because distance and travel time strongly influence the choice of hospital for this group.[8] For low-risk pregnancies at term, newborn survival is not improved by delivery in a Level II or III hospital, as compared with a Level I setting.[9,10] The relation of the birth setting to the other component of perinatal mortality in low-risk women, intrapartum fetal death, has not to our knowledge been explicitly addressed previously.

Like other infrequent pregnancy outcomes, intrapartum fetal death in low-risk women is difficult to study because few data sets contain an adequate number of cases for meaningful analysis. Although rare, intrapartum fetal death in low-risk women is a very important outcome because of the powerful emotional and psychological sequelae it generates for affected families, as well as the medical liability concerns for care providers and institutions.

The purpose of this study was to measure the frequency with which intrapartum fetal death occurs in low-risk pregnancies in the United States, and to determine whether this outcome varies according to the hospital setting for delivery.

Methods

Data source. A tape in which the 1980 National Natality Survey and National Fetal Mortality Survey are linked with an American Hospital Association annual survey of U.S. hospitals for the same year was provided as an in-house data tape, which is the property of the National Center for Health Statistics. The National Natality Survey and the National Fetal Mortality Survey sampled live births and fetal deaths from all 52 regis-

tration areas in the United States during 1980. The sampling methods and rationale are explained in detail elsewhere.[11] The sample contains 9941 live births, which represent 3,612,258 for 1980 for a sampling fraction of 1 in 363, and 6386 fetal deaths, which represent 19,202 during that year for a sampling fraction of 1 in 3. Fetal deaths were defined as those with a gestation of ≥28 weeks, or a delivery weight of at least 1000 gm. In the National Natality Survey, low-birth-weight babies were oversampled so that roughly four times the number that would have been chosen by simple random sampling were included.

Information was collected from the live birth-fetal death certificates, and then from questionnaires sent to married mothers, the hospitals of delivery, and health care providers. Data from the vital records were very nearly complete, but the mothers (20.5% in the National Natality Survey, and 25.5% in the National Fetal Mortality Survey) and the hospitals (23.9% in the National Natality Survey and 26% in the National Fetal Mortality Survey) had larger proportions of missing data. Missing entries were completed from another source when possible, and otherwise imputed by the use of specific combinations of selected predictor variables.[11] For this study, imputed data for the outcome of interest (fetal death in labor) are regarded as missing. Imputed data for the control variables were included in the study. Data in the American Hospital Association annual survey[12] allowed the examination of the outcome of labor (fetal death vs. live birth) according to certain hospital characteristics.

Study sample. The study sample was restricted to low-risk women at term because medical or obstetric conditions, as well as preterm or postterm status, may increase the likelihood of intrapartum fetal death and may also influence the choice (by the woman or her health care provider) of the hospital setting for delivery. Low-risk women are presumed to choose hospitals for reasons other than known indications for particular types of care.

Women in the National Natality Survey and the National Fetal Mortality Survey who met all the following restriction criteria constituted the low-risk study sample: gestational age, 37 to 42 weeks; maternal age, 18 to 35 years; first to fourth baby; 8 years or more of education; prenatal care beginning the first to fifth month and including at least five visits; absence of obstetric problems (breech or transverse lie, multiple gestation, hypertensive disorders); and absence of preexisting medical problems (cardiovascular, pulmonary, or renal disease; diabetes; obesity; Rh disease; sickle cell anemia; drug abuse; or alcoholism). We also excluded births that occurred out of hospital, in a hospital with no birth service, or in a hospital with no data in the American Hospital Association survey. The final sample contained 4477 live births, representing 1,821,127 in the United States for 1980, and 183 intrapartum fetal deaths, representing 556 nationally among low-risk women that year.

Hospital level. Hospital level was assigned by applying criteria from the Regionalized Perinatal Care program[13, 14] to variables in the American Hospital Association portion of the merged tape. The following definitions were used:

Level III: a teaching hospital (medical school affiliated, with American Medical Association–approved residency training programs) with a neonatal intensive care unit on-site, or a teaching hospital that performs at least 2000 deliveries annually with no on-site neonatal intensive care unit but with a formal contractual arrangement for neonatal intensive care services at a nearby facility

Level II: other urban hospitals

Level I: other rural hospitals (located in nonmetropolitan areas).

Choice of hospital for delivery is acknowledged to be nonrandom, but is primarily a function of geographic proximity if no extenuating medical or financial circumstances apply.[8]

A clear gradient of the available perinatal technology across hospital level is shown in Table I. As expected, the Level III facilities were larger, had a higher volume of deliveries, and had greater nursery capabilities. The mother's place of residence (rural-urban) and the location of the hospital for delivery were strongly associated.

Outcome. Intrapartum fetal death for this restricted group of low-risk women at term was the outcome of interest. Data were excluded for fetal deaths if death was not known with certainty to have occurred during labor.

Control variables. Ten extraneous variables that are related to intrapartum fetal death and that could vary by hospital setting and thus obscure the hospital setting–labor outcome relationship for the low-risk sample, were considered. No significant differences in number of prenatal care visits, duration of labor, labor complications, birth defects, and birth weight were found across hospital level. For maternal age, parity, maternal education, race, and marital status, small differences were found, but these were not of sufficient magnitude to confound the relationship of hospital setting to the outcome of labor to any important extent.

Analysis. For the analyses, deliveries in Level III settings were considered the reference group, the risk of fetal death in labor being lowest here. Mantel-Haenszel odds ratios and test-based 95% confidence intervals were calculated through stratified analysis for

the association of hospital level with intrapartum fetal death, comparing Level II with III and Level I with III. Crude odds ratios were compared with those adjusted individually for dichotomized control variables, to assess whether any were capable of distorting the hospital setting-labor outcome relationship.

To examine total perinatal mortality in low-risk women (including neonatal deaths), data from the 1980 National Natality Survey and the National Death Index Match Project[15] were used. This is National Center for Health Statistics data in which sampled births from the 1980 National Natality Survey were followed up in 1980 and 1981 to ascertain whether any infant deaths were reported. Sample weights were also applied to live births and intrapartum fetal deaths in the 1980 National Natality Survey and the National Fetal Mortality Survey to derive intrapartum mortality ratios (the number of fetal deaths in labor per 1000 live births) for low-risk women in the United States.

Statistical analysis was carried out with an IBM mainframe computer and software from the SAS Institute[16] at the Research Triangle Park Branch of the National Center for Health Statistics.

Results

Compared with low-risk deliveries in the Level III settings, the risk of intrapartum fetal death at Level II hospitals was twofold higher, and at Level I hospitals was 3.3-fold higher (Table II). Adjustment for the 10 dichotomized extraneous variables indicated an absence of confounding, with odds ratios after adjustment remaining consistent with the crude odds ratios. For both comparisons, slightly stronger associations were seen for primigravidas. In the Level I versus III comparison, stronger associations were seen for unmarried women and for normal birth weight babies.

To examine whether the lowered intrapartum fetal deaths in Level III settings might actually represent a postponement of death to the early newborn period (first week of life), data from the 1980 National Natality Survey and the National Death Index Match Project were examined. Of the 9941 sample births in the 1980 National Natality Survey, 295 infants died in the first year of life. Of the 4477 low-risk births in the National Natality Survey, 24 infants died during the first year, of which 16 deaths occurred in the first week of life. These were distributed as four each for Level I and II hospitals, and eight for Level III hospitals. Odds ratios and 95% confidence intervals that compare intrapartum fetal deaths and perinatal deaths (deaths occurring from labor through the first week of life) are shown in Table III. Even after consideration of early neonatal deaths, perinatal mortality for low-risk women remained lowest at Level III hospitals.

Finally, sampling weights were applied to live births and intrapartum fetal deaths in the 1980 National Natality Survey and the National Fetal Mortality Survey to derive intrapartum mortality ratios (the number of fetal deaths in labor per 1000 live births) for low-risk women in the United States (Table IV). For low-risk women in 1980, intrapartum fetal death occurred roughly once in 3300 deliveries. If these events for Level I and II are combined (474 of 1,288,820) and then compared with the ratio for Level III, the differ-

ence implies that approximately 5000 low-risk women would have to be delivered outside a Level III facility before one excess intrapartum fetal death would occur.

Comment

Intrapartum fetal death is a rare obstetric outcome, particularly for low-risk women at term. Nonetheless, if lethal anomalies are excluded, it may be at least partially preventable. This analysis showed that as the level of available perinatal technology decreased, the frequency of intrapartum fetal death in women at low risk increased. Characteristics of the childbirth setting (hospital size, volume of deliveries, teaching status, increased nursery capabilities) influenced the risk of intrapartum fetal death, even among low-risk women.

The lowered incidence of intrapartum fetal death in settings with a higher obstetric volume may indicate that medical care providers and nursing staff are able to maintain skill levels. In teaching centers, oversight or supervision mechanisms (case reviews, second opinions) may be more institutionalized. Urban hospitals may be in a more favorable position to recruit staff nurses and may have higher nurse-patient ratios for obstetrics, given that a substantial proportion of the deliveries are high risk. In small hospitals with fewer deliveries, the obstetric volume may not justify continuous staffing for a labor unit, and nurses may be moved from other clinical areas when a labor patient is admitted. In these situations, knowledge of and experience with labor surveillance may be more uneven.

This study has several limitations that require caution in interpreting the observed associations as causal. First, if unmeasured risks for intrapartum fetal death influenced hospital choice, the results would be biased. Second, our study may be in part addressing rural-urban differences. Women who reside in rural areas are known to be poorer, have reduced access to health care providers and institutions, and have higher fetal death rates.[17] Data on physician specialty (obstetrics and

gynecology or family medicine) are not available in the 1980 National Natality Survey and the National Fetal Mortality Survey. However, the relative predominance of family physicians as providers of obstetric care in rural areas is well known.[18] Third, lack of other information also limited the analysis. The data on birth defects did not permit lethal anomalies to be dropped from the analysis, and deletion of such could alter our odds ratios, although not in a predictable direction. The role of electronic fetal monitoring could not be elucidated, although two large randomized trials[19, 20] previously showed no reduction in the incidence of intrapartum fetal death by routine use of electronic monitoring. Electronic fetal monitoring was more common in cases of intrapartum fetal death than in live births (52.5% compared with 46.5%), but these data did not report the point in labor when electronic fetal monitoring was applied, or the reason for its use. Electronic fetal monitoring could have been used after the fact, to confirm fetal death. Data were also lacking on nursing care patterns. Staffing practices of obstetric nurses, nurse-patient ratios, and protocols for intermittent auscultation of the fetal heart rate would have enriched the analysis.

A final limitation is the age of the data. Changes in obstetric practice during the 1980s because of factors such as the availability and use of technology, referral patterns, the medical liability insurance crisis, and the resultant decrease in obstetric providers, particularly in rural areas, or even altered characteristics of low-risk women, might yield different results for intrapartum fetal death now.

It is of interest that the primary cesarean delivery rate for cases of intrapartum fetal death was threefold higher than for live births (28.9% compared with 10.4%) and did not vary significantly by hospital level. This decreases the likelihood that these fetal deaths occurred in the antepartum period but were incorrectly coded as intrapartum deaths. This distinction is important because reporting accuracy can strongly influence correct measurement of this rare obstetric outcome.

The proper conclusion to be drawn from our results is not that all low-risk women should be delivered in Level III hospitals, a suggestion that is neither practical nor affordable for the nation, but rather that the components of appropriate and effective intrapartum surveillance for low-risk women, characteristic of Level III hospitals, need to be delineated. Specific clinical practices, the way care is rendered, and institutional assurance mechanisms are all areas that deserve more scrutiny.

In 1988, the National Center for Health Statistics again sampled vital records for the entire U.S. The National Maternal and Infant Health Survey is scheduled to become available to researchers late in 1991. An assessment of the hospital setting–labor outcome relationship for low-risk women and an examination of time trends will then be possible with more current national data.

We wish to thank Paul Placek, PhD, and Ken Keppel, PhD, at the National Center for Health Statistics for access to the data and guidance in its use. Ron Chamblee and Donna Patten at the Technical Services Branch, RTP Branch of the National Center for Health Statistics, graciously made space available and facilitated this work in many ways. Mary D. Peoples-Sheps, DrPH, provided critical insights at the design, analysis, and interpretation stages.

Fetal ovarian cysts: Prenatal ultrasonographic detection and postnatal evaluation and treatment

Israel Meizner, MD,[a] Arie Levy, MD,[a] Miriam Katz, MD,[a] Abraham Jacob Maresh, MD,[b] and Marek Glezerman, MD[a]

Beer-Sheva, Israel

Ovarian cysts were diagnosed by antenatal ultrasonographic examination in 15 fetuses between 19 and 37 weeks' gestation. In six cases there was ultrasonographic evidence of torsion. Intracystic flocculation, which typically was deposited on the sloping part of the cyst, gave a characteristic liquid interface that was regarded as ultrasonographic evidence of torsion. All cases with evidence of torsion were managed surgically post partum, and in all patients this complication was confirmed. The remaining nine cases were followed up by repeated ultrasonograms, and in all patients disappearance of the cyst was documented within the first 6 months of life. The mean size of cysts with evidence of torsion was 5.41 ± 0.25 cm, and the mean size of those without torsion was 4.33 ± 0.3 cm ($p < 0.01$). Histologic examination of the surgical specimen in the cases with evidence of torsion revealed follicular cysts in three cases and necrotic ovarian cysts with no specific epithelial findings in the remaining three. We recommend continuous ultrasonographic assessment of antenatally diagnosed cysts and believe that the choice of treatment depends on the appearance of the cyst and its evolution throughout pregnancy. (Am J Obstet Gynecol 1991;164:874-8.)

Key words: Ovarian cyst, torsion, ultrasonography

Small ovarian cysts in the newborn are not uncommon. DeSa[1] found small follicular cysts in 113 (34%) of 332 stillborns or infants who died within 28 days of birth. Doshi et al.[2] reported similar findings in 32% of 40 neonates at autopsy in their series. Most of these small cysts involute within the first few months of life and have no clinical significance. Occasionally, however, a large ovarian cyst is seen as an abdominal mass in the newborn. Because of progress in ultrasonography, it has become possible to assess the antenatal evolution of these cysts. Timely alertness of pediatric surgeons will then permit early neonatal intervention. Only a few cases of antenatal ultrasonographic diagnosis of fetal ovarian cysts have been reported,[3-6] but the therapeutic aspects in these cases have been rarely documented. We present our experience with the diagnostic and therapeutic aspects of antenatally diagnosed ovarian cysts.

Material and methods

Fetal ovarian cysts were diagnosed in 15 cases in our ultrasound unit during the period between Nov. 1, 1987, and March 31, 1990. Ten of these 15 cases were diagnosed during routine scans, and five were referred on the basis of a nonspecific diagnosis (made elsewhere) of a fetal abdominal mass.

These criteria were used in identifying ovarian cysts: (1) presence of a cystic structure that was regular in shape and usually located on one side of the fetal abdomen, (2) integrity of urinary and gastrointestinal tracts, and (3) female sex of the fetus (Fig. 1). The diagnosis was always presumptive, since rare lesions such as mesenteric cysts, urachal cysts, or enteric duplications could not be ruled out with absolute certainty. A careful ultrasonographic survey of the entire fetal anatomy, including the heart, was performed in all cases. Attention was paid to cyst septation or bilaterality. Torsion was assumed if intracystic flocculation was observed, which was followed by sedimentation on the sloping part of the cyst. This sedimentation gives a characteristic liquid interface (Fig. 2).[7] The volume of the ovarian cysts was calculated with the formula for determining the volume of a sphere ($4/3\ \pi\ r^3$). The radius was calculated as (D1 + D2 + D3)/6. The patients were followed up by a multidisciplinary team with a specialty in fetal anomalies. This team included an obstetrician, a neonatologist, a pediatric surgeon, a social worker, and a geneticist. Postnatal follow-up was carried out in all cases.

Results

Of the 15 cases of fetal ovarian cysts that were diagnosed prenatally, nine did not show any ultrasono-

graphic evidence of torsion (Table I). Gestational age at the time of diagnosis in these cases ranged from 19 to 35 weeks of pregnancy. In four cases the cystic mass was bilateral (Fig. 3). The cysts were unilocular and were without internal echoes or fluid levels. The largest was 6 × 7 × 4 cm.

In the remaining six cases evidence of torsion was observed (Table II). Gestational age at the time of diagnosis ranged from 19 to 37 weeks of pregnancy. In these cases internal echoes and fluid levels were seen, both of which suggested torsion. All cases were unilateral, and one cyst (Case 10) was multilocular. The mean diameter of the cysts in this group was 5.41 ± 0.25 cm, as compared to that of the group without torsion, which was 4.33 ± 0.3 ($p < 0.01$).

Patients were delivered of infants spontaneously in 13 cases, cesarean sections were performed in 2 cases (one of fetal distress and the other of placenta previa). All newborn were in good condition with normal Apgar scores. Each newborn weighed >2500 gm. There were no additional anomalies. The ultrasonographic scans performed during the neonatal period were consistent with the diagnosis of fetal ovarian cyst in all 15 cases. Postnatal ultrasonographic findings of the nine cases with no evidence of torsion were confirmed postnatally (Table I). In seven of these nine cases the cysts involuted within 2 months of follow-up, and in the remaining two cases the cysts disappeared within 6 months. There was no absolute proof that the cysts were indeed of ovarian origin. However, a regressing cystic lesion in a female newborn makes this diagnosis highly probable.

In six cases ultrasonography performed immediately after delivery confirmed the impression of torsion in ovarian cysts (Table III). The diagnosis was confirmed during operation (Fig. 4). In four cases adnexectomy was performed, and in one case excision of the cyst was sufficient. One of the cysts (case 12) was found to be detached from its origin as the result of ischemia of the fetal adnexa, and thus was identified as a "wandering" cyst. Histologic examination revealed follicular cysts in three cases and necrotic ovarian cysts with no specific epithelial findings in the remaining three cases. In all cases there was no evidence of cystic lesions in the contralateral ovary.

Comment

Except for large cysts and those complicated by torsion or hemorrhage, fetal ovarian cysts and tumors have not been recognized until recently, when an increase in the use of obstetric ultrasonography has made possible the earlier and more frequent diagnosis of ovarian cyst.

In eight of our patients the antenatal diagnosis of an ovarian cyst was made before the 28th week of gestation. We could not find any reports in the literature

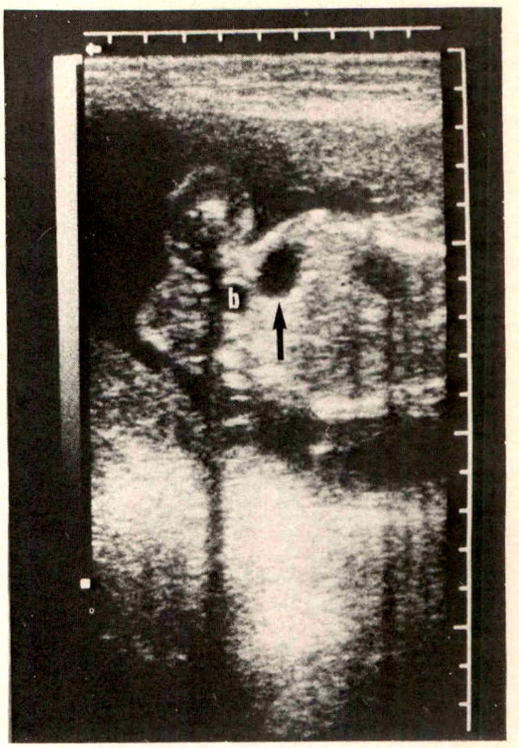

Fig. 1. Longitudinal scan of fetus at 20 weeks of gestation with small ovarian cyst *(arrow)*. *b*, Bladder.

that pertained to prenatal diagnosis of ovarian cysts before the third trimester of pregnancy.[5-9] Fetal ovarian cysts are the most common cause of an intraabdominal cyst that is observed antenatally (excluding those of renal and gastrointestinal etiology).[8] There is controversy with respect to the genesis of fetal ovarian cysts. Evidence suggests that excessive stimulation of the fetal ovary by both placental hormones and maternal hormones may be a significant factor in cyst development. Such stimulation would explain an increased incidence of cysts in the infants of mothers with diabetes, toxemia, or rhesus isoimmunization, presumably from excessive release of placental chorionic gonadotropins by the enlarged placenta.[10, 11] Suggested hypotheses include a precocious follicle-stimulating hormone peak between the 20th and 30th weeks of gestation, an abnormal human chorionic gonadotropin peak that would explain the observation of fetal ovarian cysts in pregnancies with increased secretion (perhaps from maternal diabetes or rhesus isoimmunization), or a disorder of enzyme activity in the internal theca. An association between the development of ovarian cysts and fetal hypothyroidism has also been suggested on the basis of nonspecific stimulation of pituitary glycoprotein hormone synthesis.[11, 12] None of the above hypotheses has been formally proved. In our present series there were no mothers with diabetes and the weight of each pla-

centa ranged within the normal limit of one sixth to one fifth of each infant's respective birth weight. Sedin et al.[13] suggested that in premature babies estradiol-producing ovarian cysts may occur from inadequate negative feedback that results in ovarian hyperstimulation.

The ultrasonographic diagnosis of a rounded, intraabdominal liquid mass in a female fetus permits the longitudinal observation of these cysts. These cysts may either regress with no sequelae or remain stable. None of our cases showed antenatal regression. In one case a sudden development of intense hyperechogenicity

11	Left cystic mass	Excision	Necrotic cyst
12	Right floating cystic mass	Removal	Necrotic cyst
13	Left adnexa replaced by cystic mass	Left adnexectomy	Follicular cyst
14	Left cyst with torsion	Left adnexectomy	Follicular cyst
15	Left cyst with torsion	Excision	Necrotic cyst

within the cyst, which was followed by a complex, heterogeneous appearance, was interpreted as the consequence of intrauterine torsion of the cyst with infarction. Torsion may be assumed when the presence of intracystic flocculation is followed by sediment that is deposited on the sloping part of the cyst, which gives a characteristic liquid interface.

Ultrasonography can accurately depict intracystic hemorrhage and necrosis. The ultrasonographic criteria for torsion were found to be reliable in all six cases and were confirmed at operation. Torsion may lead to necrosis of the pedicle and may thus cause a "wandering" tumor (case 3).[14]

All nine cysts without ultrasonographic signs of torsion regressed spontaneously during the first 6 months after delivery. This may be the general tendency of uncomplicated cysts. Therefore in these simple cysts ultrasonographic assessment during the first months of life should be the only measure taken. On the other hand, when ultrasonographic criteria indicate torsion, prompt surgical intervention immediately after delivery is the treatment of choice. Puncturing appears dangerous (frequent multiple pericystic adhesions may result) or impossible (where the content is of organized-coagulum type). The surgeon should try to preserve ovarian parenchyma whenever possible, but the state of adnexa and ovary often leaves no choice other than adnexectomy (Fig. 4).

The tendency of simple cysts to regress near term or in the early neonatal period does not justify in utero therapy and certainly does not necessitate induction of labor before lung maturity is ascertained. However, there are reports in the literature of ruptured cysts that required emergency laparotomy.[15] Therefore it was suggested that when a large ovarian cyst is suspected in a mature fetus, consideration should be given to a cesarean section to avoid the risks of torsion or rupture of the cyst.[16] Fetal ovaries that show ultrasonographic signs of torsion tend to have a poor outcome. If a simple fetal ovarian cyst begins to show signs of recent torsion

during follow-up and if the fetus is deemed viable, induction of labor may be considered to permit early surgical intervention in an effort to save an ovary.

In conclusion, fetal ovarian cysts can be diagnosed by ultrasonography early in pregnancy. Follow-up and assessment are possible throughout gestation. It seems to us that management depends on the antenatal ultrasonographic appearance of the cyst and on its evolution throughout pregnancy. Cysts without strict ultrasonographic evidence of torsion should be managed carefully after delivery. However, prenatal ultrasonographic evidence of torsion confirmed postnatally is an indication for prompt postnatal intervention.

A comparison of flurbiprofen, tranexamic acid, and a levonorgestrel-releasing intrauterine contraceptive device in the treatment of idiopathic menorrhagia

Ian Milsom, MD, Kerstin Andersson, MD, Björn Andersch, MD, and Göran Rybo, MD
Göteborg, Sweden

Treatment with flurbiprofen (100 mg twice a day for 5 days), tranexamic acid (1.5 gm three times a day for 3 days and 1 gm twice a day for another 2 days), and an intrauterine contraceptive device releasing 20 μg levonorgestrel per day was compared in women with idiopathic menorrhagia. The menstrual blood loss during two control periods in 15 women subsequently treated with flurbiprofen and tranexamic acid was 295 ± 52 ml and 203 ± 25.2 ml in the 16 women later fitted with a levonorgestrel-releasing intrauterine contraceptive device. Menstrual blood loss was reduced by all three forms of treatment. The reduction in menstrual blood loss expressed as a percentage of the mean of two control cycles for each form of treatment was as follows: flurbiprofen, 20.7% ± 9.9%; tranexamic acid, 44.4% ± 8.3%; levonorgestrel-releasing intrauterine contraceptive device after 3 months, 81.6% ± 4.5%; levonorgestrel-releasing intrauterine contraceptive device after 6 months, 88.0% ± 3.1%; levonorgestrel-releasing intrauterine contraceptive device after 12 months, 95.8% ± 1.2%. The reduction in menstrual blood loss achieved by the levonorgestrel-releasing intrauterine contraceptive device was greater than that recorded with flurbiprofen ($p < 0.001$) and tranexamic acid ($p < 0.01$), and was greater for tranexamic acid when compared with flurbiprofen ($p < 0.05$). The levonorgestrel-releasing intrauterine contraceptive device was the only form of treatment to reduce mean menstrual blood loss below 80 ml per menstruation, the upper limit of normal menstrual blood loss. (Am J Obstet Gynecol 1991;164: 879-83.)

Key words: Menorrhagia, treatment, intrauterine contraceptive device, levonorgestrel, tranexamic acid, flurbiprofen

Approximately 10% of healthy women suffer from menorrhagia, defined as a menstrual blood loss of >80 ml.[1] Excessive menstrual blood loss may lead to iron-deficiency anemia and ultimately necessitate hysterectomy.[2, 3] Almost half a million hysterectomies are performed each year in the United States because of menstrual disorders[4] and it has been reported that >18,000 hysterectomies are performed in England each year solely because of menorrhagia.[5] Since operative treatment carries a not insignificant risk of morbidity and mortality, various forms of medical treatment have been advocated as the first line of treatment. Antifibrinolytic agents, prostaglandin synthetase inhibitors, oral contraceptives, and the intrauterine release of progestogens have all been shown to be effective in the treatment of idiopathic menorrhagia.[6-10]

The aim of this study was to objectively evaluate three principally different forms of medical treatment for idiopathic menorrhagia. The effect of treatment with flurbiprofen, a prostaglandin synthetase inhibitor; tranexamic acid, an antifibrinolytic agent; and intrauterine release of levonorgestrel by means of an intrauterine contraceptive device (IUD) were compared.

Material and methods

Thirty-five women who sought medical attention because of heavy menstrual bleeding with a menstrual blood loss of >80 ml during two pretreatment periods were invited to participate in this study. Only patients judged to have idiopathic menorrhagia were included. The women had a normal-sized or only slightly enlarged uterus and no signs of pelvic pathologic conditions as judged by gynecologic examination. Patients with menorrhagia caused by pelvic pathologic conditions, e.g., palpable fibroids diagnosed by gynecologic examination, were excluded. The women were otherwise healthy, had regular menstrual cycles, had not used oral contraceptives or an IUD, and had not been pregnant during the 2 months before inclusion. The women gave informed consent and the study was approved by the Medical Ethics Committee, University of Göteborg.

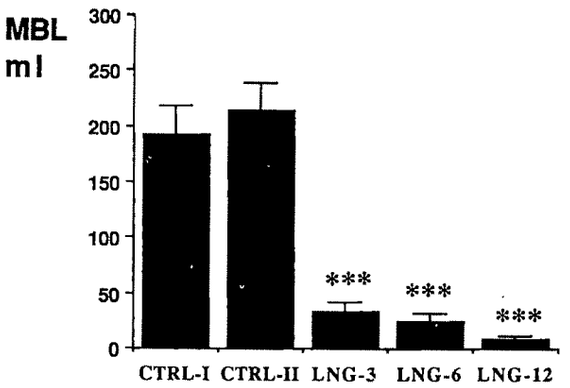

Fig. 1. Menstrual blood loss *(MBL)* in 16 women with idiopathic menorrhagia treated with a levonorgestrel-releasing IUD *(LNG)*. Menstrual blood loss was determined during two medication-free control cycles *(CTRL)* and 3, 6, and 12 months after insertion. Significance of difference between control cycles and during treatment with levonorgestrel-releasing IUD indicated by *triple asterisks* ($p < 0.001$).

The first twenty consecutive women (age, 37.8 ± 0.9 years; range, 31 to 45 years; and parity, 2.2 ± 0.2, range 1 to 4) were treated by the intrauterine release of levonorgestrel (LNG-IUD, Leiras, Turku, Finland). The levonorgestrel-releasing IUD used in this study has the same T-shaped polyethylene skeleton as the Nova-T IUD. The steroid is homogeneously dispersed in a polydimethyl-siloxane reservoir covered by a rate-limiting membrane on the vertical arm of the device. The total amount of levonorgestrel in the IUD is 46 mg and the release rate is 20 μg/day. This IUD has an estimated effective life span of 5 years. Measurement of menstrual blood loss was performed during two consecutive periods before IUD insertion and 3, 6, and 12 months after insertion.

Fifteen women (age, 40.5 ± 1.1 years, range 34 to 49 years; and parity 1.7 ± 0.2, range 0 to 3) were then treated with flurbiprofen and tranexamic acid during four consecutive menstrual periods according to a randomized, open-crossover study design. Measurements of menstrual blood loss during two control cycles were first performed. Menstrual blood loss was also determined during the subsequent four cycles during which the women received either oral tranexamic acid (1.5 gm three times daily for 3 days and 1 gm twice daily for another 4 days) or flurbiprofen (100 mg twice daily for 5 days). Treatment was started on the first day of menstruation; each patient received one compound for two menstrual periods and then the other for a further two menstrual periods. Medication was supplied in individual patient packs and compliance was checked by counting the remaining tablets after each course of treatment.

All women were requested to record details of the menstrual cycle (dates of last menstrual period, duration of menstruation, possible intermenstrual bleeding) and any side effects. No additional medication was allowed and patients did not receive iron supplementation during the study. The venous concentration of hemoglobin was measured each month after menstruation.

The women were supplied with polyethylene bags for each menstrual period in which the used sanitary pads and tampons were collected daily. The bags were delivered to the laboratory after the period. Menstrual blood loss was determined by spectrophotometric analysis of alkaline hematin as described by Hallberg and Nilsson[11] and modified by Newton et al.[12]

Statistical analysis. The results are expressed as mean ± SEM. A linear nonparametric test and Fisher's least significant difference test were used to evaluate statistical significance ($p < 0.05$ was considered significant).

Results

Sixteen of the 20 women fitted with a levonorgestrel-releasing IUD completed the 12-month observation period. One woman was excluded from the study because of expulsion of the IUD during the first menstrual cycle after insertion. She was 41 years old, para 3, and menstrual blood loss was 550 and 449 ml before insertion. A hysterectomy was later performed. The endometrium was normal at histopathologic examination, apart from the presence of small submucous fibroids. In two women the IUD was removed before the 6-month follow-up because of intermenstrual bleeding. One woman had the levonorgestrel-releasing IUD removed after 10 months because of acne, weight gain (2.5 kg), mood changes, and intermenstrual bleeding.

Menstrual blood loss during the two control periods for the women who subsequently completed the study was 203 ± 25.2 ml (range, 80 to 381 ml), decreasing ($p < 0.001$) to 34 ± 8.5 ml (range, 0 to 145 ml) after 3 months, 25 ± 7.3 ml (range, 0 to 119 ml) after 6 months, and 9 ± 2.7 ml (0 to 33 ml) after 12 months (Fig. 1). Intermenstrual bleeding or spotting was reported by most women during the first three cycles after insertion, but the frequency diminished gradually. The amount of blood loss by spotting was estimated by the women to be very small and was not measured. Seven women subsequently developed amenorrhea.

Menstrual blood loss during the medication-free menstrual cycles was 295 ± 52 ml (range, 81 to 701 ml) in the women subsequently treated with flurbiprofen and tranexamic acid (Fig. 2). The difference in menstrual blood loss before treatment between women later fitted with a levonorgestrel-releasing IUD and women treated with flurbiprofen and tranexamic acid was not statistically significant. Treatment with flurbi-

profen reduced ($p < 0.05$) mean blood loss to 223 ± 44 ml (range, 50 to 636 ml). The mean blood loss was reduced ($p < 0.01$) to 155 ± 33 ml (range, 36 to 511 ml) during treatment with tranexamic acid. Treatment with tranexamic acid or flurbiprofen did not alter the duration of menstrual flow and there were no reported episodes of intermenstrual bleeding. Seven of 15 women complained of side effects which they attributed to the given medication during treatment with tranexamic acid. Four of the 15 women complained of side effects during the flurbiprofen cycles. Treatment with tranexamic acid caused nausea, dizziness, numbness, "restless legs," headache, and, in three women, vomiting and difficulty in swallowing. Flurbiprofen caused tiredness, stomach pains, and nausea. No patient discontinued therapy with either flurbiprofen or tranexamic acid because of side effects.

The reduction in menstrual blood loss expressed as a percentage of the mean of two control cycles for each form of treatment is shown in Fig. 3. Menstrual blood loss reduction was greater with the levonorgestrel-releasing IUD compared with flurbiprofen ($p < 0.001$) or tranexamic acid ($p < 0.01$) and with tranexamic acid compared with flurbiprofen ($p < 0.05$).

The hemoglobin concentration during the control cycles (127.4 ± 3.7 gm/L) did not differ significantly from the recorded hemoglobin concentration during treatment with flurbiprofen (127 ± 3.4 gm/L) and tranexamic acid (126 ± 3.0 gm/L). The hemoglobin concentration for women subsequently fitted with a levonorgestrel-releasing IUD was 127 ± 2.6 mg/L and increased to 138 ± 2.1 mg/L after 6 months ($p < 0.05$) and to 139 ± 3.2 mg/L after 12 months ($p < 0.01$).

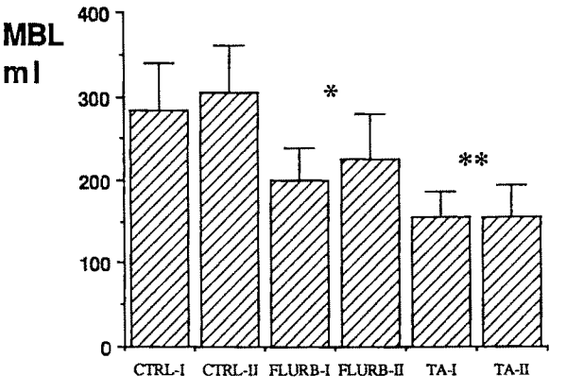

Fig. 2. Menstrual blood loss *(MBL)* in 15 women with idiopathic menorrhagia before and during treatment with flurbiprofen (100 mg twice daily for 5 days) and tranexamic acid (1.5 gm three times a day for 3 days and 1 gm twice daily for days 4 and 5). Significance of difference between control cycles *(CTRL)* and during treatment with flurbiprofen *(FLURB)* and tranexamic acid *(TA)* indicated by *asterisk* ($p < 0.05$) and *double asterisks* ($p < 0.01$).

Comment

In this study menstrual blood loss during two medication-free menstrual periods was well in excess of the clearly defined limit of 80 ml per menstrual period used in the definition of menorrhagia.[1] All patients included were deemed to be suffering from idiopathic menorrhagia by exclusion of gross pelvic pathologic conditions.

Increased fibrinolytic activity has been implicated as a cause of idiopathic menorrhagia.[13] Prostaglandins have also been shown to play an important role in the regulation of menstrual bleeding. Several reports have demonstrated an increased endometrial concentration of prostaglandins in women with dysfunctional bleeding and menorrhagia.[14, 15]

Antifibrinolytic agents are well established in the treatment of menorrhagia and have been shown to be highly effective in reducing excessive menstrual bleeding.[6] A variety of prostaglandin synthetase inhibitors have also been shown to be effective in the treatment of menorrhagia.[5, 16, 17] The doses of flurbiprofen and tranexamic acid used in this study are those presently used in clinical practice and have previously been shown to be optimal for the effective treatment of idiopathic menorrhagia.[6, 9, 17] Higher doses of tranexamic acid have been shown to reduce menstrual blood loss even more but are unfortunately associated with an increasing frequency of side effects such as nausea and gastric irritation. The use of intrauterine progesterone has been shown to be effective in the treatment of menorrhagia[8] and is associated with suppression of the endometrium caused by progesterone.[18]

In this study both flurbiprofen and tranexamic acid reduced menstrual blood loss in patients with idiopathic menorrhagia. However, neither substance reduced the mean menstrual blood loss to <80 ml. The reduction in menstrual blood loss was significantly greater during treatment with tranexamic acid compared with flurbiprofen. This may indicate that endometrial fibrinolysis, rather than prostaglandin release, is of greater importance as a cause of menorrhagia. Ylikorkala and Viinikka[17] compared antifibrinolytic and antiprostaglandin treatment in women with IUD-induced excessive menstrual blood loss. Treatment with tranexamic acid reduced menstrual blood loss by 56%, whereas the prostaglandin synthetase inhibitor diclofenac sodium reduced menstrual blood loss by 24%. Similar results were recorded in this study in patients with idiopathic menorrhagia. Tranexamic acid reduced menstrual blood loss by 44%, whereas treatment with the prostaglandin synthetase inhibitor flurbiprofen reduced menstrual blood loss by 21%.

The levonorgestrel-releasing IUD reduced menstrual blood loss to levels well below 80 ml. The

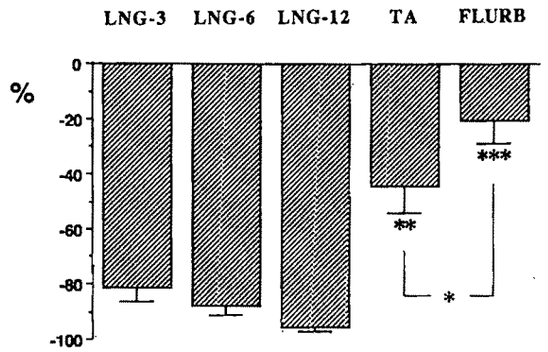

Fig. 3. Reduction in menstrual blood loss expressed as percentage of mean of two control cycles for each form of treatment. Significance of difference between treatment with levonorgestrel-releasing IUD *(LNG)* and tranexamic acid *(TA)* and flurbiprofen *(FLURB)* indicated by *double asterisks* ($p < 0.01$) and *triple asterisks* ($p < 0.001$) and between treatment with tranexamic acid and flurbiprofen indicated by *asterisk* ($p < 0.05$).

reduction in menstrual blood loss achieved by the levonorgestrel-releasing IUD was greater than that recorded during treatment with flurbiprofen and tranexamic acid. Levonorgestrel is not metabolized by the endometrium as rapidly as progesterone and has a more uniform and profound local effect.[19] The use of progesterone in an IUD (Progestasert) has been shown to decrease menstrual blood loss by 65% after 12 months of treatment in women with menorrhagia.[8] The levonorgestrel-releasing IUD used in the present study reduced menstrual blood loss by 82% after 3 months and by 96% after 12 months. It is known that the levonorgestrel-releasing IUD can cause amenorrhea in some women.[20] In seven of the women included in this study amenorrhea subsequently developed.

Conventional copper-bearing IUDs are a common form of birth control worldwide, but their use in the United States has been limited, mainly because of the reported risk of upper genital tract infections.[21] The use of the levonorgestrel-releasing IUD has been shown to be associated with a lower frequency of pelvic inflammatory disease than a conventional copper-bearing IUD.[20] A possible explanation for this observation is the local effect of the progestogen on the endometrium and cervical mucus, which provides protection against ascending infections. Further, long-term studies are at present being performed to compare the influence of the levonorgestrel-releasing IUD with copper IUDs regarding the risk of developing pelvic inflammatory disease.

There is no doubt that hysterectomy is a highly effective way of treating menorrhagia, but operative morbidity and long-term morbidity cannot be considered to be insignificant.[22] Can hysterectomy be justified if alternative, simpler treatment forms become available? Selective endometrial destruction with laser or electrocoagulation may in the near future provide a useful alternative to hysterectomy. However, there are at present few published reports of follow-up after endometrial resection.[23]

This study has demonstrated a reduction in menstrual blood loss by all three, principally different, medical treatment regimes under investigation. The levonorgestrel-releasing IUD reduced menstrual bleeding more than flurbiprofen and tranexamic acid, and was the only form of treatment to reduce menstrual blood loss to normal levels, i.e., <80 ml per menstrual period. The overall frequency of side effects with the levonorgestrel-releasing IUD was low. Our results strongly support the use of a levonorgestrel-releasing IUD as a useful alternative to hysterectomy for many women with idiopathic menorrhagia.

We wish to express our thanks to Mölnlycke AB for the kind donation of the pads used in this study.

Position change and central hemodynamic profile during normal third-trimester pregnancy and post partum

Steven L. Clark, MD,[a, b] David B. Cotton, MD,[c] James M. Pivarnik, PhD,[c] Wesley Lee, MD,[c] Gary D.V. Hankins, MD,[d] Thomas J. Benedetti, MD,[e] and Jeffrey P. Phelan, MD[f]

Salt Lake City, Utah, Houston and San Antonio, Texas, Seattle, Washington, and Los Angeles, California

Central hemodynamic response to position change was assessed in 10 normotensive primiparous patients between 36 and 38 weeks' gestation. Studies were repeated between 11 and 13 weeks post partum. Compared with the left lateral position, we observed a mean 9% fall in cardiac output in the supine position and an 18% fall when patients were standing. When standing, these patients had a 30% increase in pulse and a 21% fall in left ventricular stroke work index. The orthostatic response after pregnancy was much more labile than that during the third trimester. These findings have important descriptive implications for the understanding of the human response to orthostasis during pregnancy, as well as clinical implications for patients at risk of uteroplacental insufficiency and for working women during pregnancy. (AM J OBSTET GYNECOL 1991;164:883-7.)

Key words: Hemodynamics of pregnancy, pulmonary artery catheter, critical care

Pregnancy brings about profound alterations in maternal hemodynamics.[1] The central hemodynamic profile of the pregnant woman is further altered by position changes, compounded in late pregnancy by the effects of the gravid uterus on vena caval and aortic blood flow in the supine position.[2] Whereas partial hemodynamic descriptions of select postural changes in pregnancy exist, these lack complete data with regard to preload of the left and right sides of the heart, pulmonary vascular pressures, and left ventricular function or have relied on noninvasive assessment of cardiac output.[2, 3] We present a systematic description of the effects of position change on maternal central hemodynamics with the use of the Fick principle to assess cardiac output and pulmonary artery catheterization to measure central pressures.

Material and methods

Ten volunteers were studied. Each met criteria detailed in Table I.

Written informed consent was obtained. The study was approved by the hospital Institutional Review Board and an outside reviewer (pulmonologist-intensivist). Subjects were reimbursed $200.00 for participation in each phase (pregnant and nonpregnant) of the study. Four subjects who volunteered were excluded before initiation of the study because of borderline anemia, fetal intrauterine growth retardation, or the development of elevated blood pressure before

Table I. Study inclusion criteria

Primiparous
Maternal age <26 years
Singleton vertex fetus
Gestational age between 36 and 38 weeks confirmed by ultrasonography
No fetal intrauterine growth retardation or anomalies
Normal amniotic fluid volume
Normal maternal weight for height
Normal maternal hematocrit values
No maternal alcohol, tobacco, or drug use
No maternal hypertension, medical illness, or medications

the study. Subjects were initially recruited from physicians' offices in Provo, Utah. The study was performed at the Utah Valley Regional Medical Center in Provo, altitude 4540 feet.

Each subject underwent pulmonary artery catheterization via the subclavian route and radial arterial line placement. Venous access was established by means of a peripheral heparin lock venous catheter. Baseline hemodynamic assessment was made with subjects in the left lateral recumbent position after a 30-minute stabilization period. A 10-minute premeasurement stabilization period was allowed between each position change. Cardiac output was measured with the use of the direct Fick technique. Oxygen consumption was measured continuously with the open circuit technique with a metabolic cart (Sensormedics model 4400, Anaheim, Calif.). Before each test, the metabolic analyzers were calibrated with certified standard gases of known concentrations verified by the micro-Scholander technique. When each subject's oxygen consumption values stabilized (after 10 minutes), blood samples were obtained simultaneously from the pulmonary and radial arteries. Care was taken to clear the lines before drawing blood to prevent dilution of samples. Blood samples were analyzed in duplicate for oxygen content on a blood gas analyzer (Corning Model 168, Medfield, Mass.). Calibrations were performed before each subject was tested and routinely throughout each experiment. Central pressures were measured and recorded with a 10-channel physiologic monitor-recorder (Hewlett Packard model 7785 B, Waltham, Mass.). Central pressures presented here represent the mean during three consecutive respiratory cycles as measured in end expiration from the tracing. Monitors were rezeroed in each position with transducer placement at the level of the left atrium confirmed by simultaneous real-time maternal echocardiography. Studies were repeated in each subject between 11 and 13 weeks post partum.

Results

Table II describes hemodynamic changes that occur as a result of position change in the pregnant woman. Table III describes such changes in the same women after pregnancy. In pregnant patients, we observed a mean 9% fall in cardiac output associated with assumption of the supine position ($p < 0.05$) and a mean 18% fall on assumption of the standing position ($p < 0.05$) compared with the left lateral position. There was no significant change in cardiac output in the right lateral or knee-chest positions compared with the left lateral position. A decrease in cardiac output was also seen in the sitting position; however, this did not reach statistical significance (Fig. 1). No change in heart rate was observed on assumption of the supine position in these subjects. However, a 30% increase in pulse, a 21% fall in left ventricular stroke work index, and a 54% rise in pulmonary vascular resistance was noted after standing ($p < 0.05$). No significant change was seen in mean systemic vascular resistance, mean arterial pressure (MAP), pulmonary capillary wedge pressure, central venous pressure, or mean pulmonary artery pressure with any position change, although a trend was observed toward a fall in central venous pressure with standing and a rise in central venous pressure with assumption of the knee-chest position.

After pregnancy, no change in any hemodynamic parameter was seen in the supine position, as compared with the left lateral position. A 31% fall in cardiac output, a 27% rise in heart rate, a 42% rise in systemic vascular resistance, a 106% rise in pulmonary vascular resistance, and a 22% fall in left ventricular stroke work index were observed when standing ($p < 0.05$). No significant change was seen in MAP, pulmonary capillary wedge pressure, central venous pressure, or mean pulmonary artery pressure.

Comment

The human response to orthostasis is complex. Major mediators of this response appear to be the carotid baroreceptors, which respond to decreased stretch by increasing adrenergic sympathetic output with resultant changes in heart rate and arterial resistance vessels.[4] These changes serve to maintain blood pressure despite an orthostatic fall in cardiac output. In contrast, venous capacitance vessels behave in a predominantly passive manner; the existence of venoconstriction in response to orthostasis is controversial and if present it is quantitatively of little significance.[4, 5] A fall in renal blood flow and glomerular filtration rate resulting in increased blood volume is also seen in response to orthostasis; similarly, blood volume decreases in the recumbent position.[4, 6, 7] Although they do not have an immediate hemodynamic effect, these renal excretory responses are extremely sensitive, and compared with the sluggish response in venous tone, imply that in human beings volume is adjusted preferentially to capacity.[4]

Our data indicate that during pregnancy, hemodynamic mechanisms are altered significantly. The major factors involved are decreased systemic vascular resistance and expansion of venous capacitance of the developing uteroplacental vascular bed and a 40% to 50% increase in intravascular volume and cardiac output.[1, 8] We observed a significant fall in cardiac output in response to orthostasis during pregnancy; the 30% increase in pulse was insufficient to compensate for declining stroke volume. These findings are similar in magnitude to those observed by Easterling et al.[3] with the use of Doppler cardiac output assessment. The fall in left ventricular stroke work index suggests a concomitant decrease in intrinsic ventricular function during orthostasis, almost certainly a result of Starling forces. However, these changes were far less than the orthostatic changes observed in the same patients while not pregnant (Fig. 2). Although MAP and mean pulmonary artery pressure were maintained during orthostasis after pregnancy, this was at the expense of

dramatic increases in systemic vascular resistance (42%) and pulmonary vascular resistance (106%), changes of a degree not seen during pregnancy. Thus the stabilizing effects of increased intravascular volume during pregnancy are relatively greater than the somewhat opposite effects of increased venous capacitance and decreased systemic vascular resistance. This implies a greater hemodynamic stability in response to orthostasis during pregnancy despite a reported blunting of norepinephrine secretion in response to orthostatic stress.[9, 10] In nonpregnant human beings, response to orthostatic stress is similarly enhanced by increasing blood volume.[4] Such a condition would have important effects on the maintenance of constant uteroplacental blood flow because orthostasis, as opposed to recumbency, is in fact the dominant body position during pregnancy.

It was surprising that cardiac output during the late phase of pregnancy was actually lower in the standing position than that in the supine position. Whereas avoidance of the supine position has long been a mainstay of the management of the late phase of pregnancy, these results have significant negative implications in terms of cardiac output and uteroplacental perfusion for working women who must stand motionless for long periods of time (for example a bank teller or cashier). This would especially apply to women who otherwise are at risk of uteroplacental insufficiency. These results

give a physiologic basis for findings by Naeye et al. of decreased birth weight and placental infarction in working mothers who stand.[11] Potentially harmful effects of standing on decreased cardiac output would likely be negated by ambulation or exercise.

In the supine position, cardiac output falls significantly during the late phase of pregnancy because of vena caval and aortic compression by the pregnant uterus and resultant decreased venous return. The actual change is partially dependent on the degree of paravertebral collateral circulation that is available for returning blood from the lower extremities and pelvis to the heart. Our results with the Fick cardiac output assessment confirmed data obtained with noninvasive techniques.[3] Because the vena cava is located on the right of the descending aorta, the left lateral position has often been assumed to be the position of optimal cardiac output during the late phase of pregnancy. Whereas we confirmed the potentially deleterious effects of the supine position on cardiac output, we were unable to show any benefit (in terms of cardiac output) of left versus right lateral recumbent positions.

It is of interest that the rise in pulmonary vascular resistance necessary to maintain mean pulmonary artery pressure in the face of falling cardiac output was proportionately much greater than the rise in systemic vascular resistance necessary to maintain MAP with the same decrease in cardiac output. This was observed both during and after pregnancy. During pregnancy, we observed a 54% increase in pulmonary vascular resistance compared with a 9% rise in systemic vascular resistance with orthostasis, with no change in mean pulmonary artery pressure or MAP. After pregnancy, orthostasis resulted in a 106% rise in pulmonary vascular resistance and a 42% rise in systemic vascular resistance with no change in pulmonary or systemic pressures. These changes highlight the extremely labile nature of pulmonary vascular resistance compared with systemic vascular resistance during pregnancy. Such a feature is essential given the physiologic imperative to avoid on a minute-to-minute basis, ventilation-perfusion mismatch, and to effect appropriate recruitment of nonperfused vessels in the upper lungs, according to an ever-changing physiologic milieu. Such a labile system would be especially vital during a period of profound hemodynamic change, such as pregnancy, labor, and delivery. This may help explain why women with fixed pulmonary vascular resistance and pulmonary hypertension often tolerate so poorly the hemodynamic fluctuations associated with pregnancy and delivery.[12]

Nonsurgical management of tubal pregnancy

Necessity in view of the changing clinical appearance

M. Pansky, MD, A. Golan, MD, I. Bukovsky, MD, and E. Caspi, MD
Tel Aviv, Israel

The incidence of ectopic pregnancy is definitely increasing. Ectopic pregnancies are diagnosed earlier these days because of the improvement in diagnostic means and the increasing awareness of the condition. It seems that there is a dramatic change in the clinical presentation of this disease; it used to be a grave and life-threatening condition, and now it is a more benign presentation. The vast majority of the diagnosed ectopic pregnancies are unruptured. This has stimulated various investigators to attempt nonsurgical methods of treatment such as systemic administration of methotrexate or RU 486 (mifepristone) or local injection of methotrexate, potassium chloride, or prostaglandins under laparoscopic or ultrasonographic guidance. Most of these conservative, nonsurgical measures proved efficient in 80% to 90% of cases. Expectant management, which was practiced in some cases, proved to be equally successful. We believe that the ideal mode of treatment in early unruptured ectopic pregnancy is still to be determined. The answer probably lies in proper selection. (Am J Obstet Gynecol 1991;164:888-95.)

Key words: Nonsurgical management, tubal pregnancy

The incidence of tubal pregnancy has undoubtedly been increasing and has even been described as an epidemic.[1] During the past 10 years, the incidence of ectopic pregnancy increased in our medical center from 1 of every 136 deliveries in 1979 to 1 of every 79 in 1989.

Some recent developments may explain this increasing incidence. First, the rising incidence of pelvic inflammatory disease, liberal use of tuboplastic and conservative operations for tubal pregnancy, and an increased use of agents to induct ovulation and in vitro fertilization–embryo transfer techniques[2]; second, there has been a dramatic improvement in the means of diagnosis, such as laparoscopy, sensitive β human chorionic gonadotropin (β-hCG) assays in urine and blood, and improvements in ultrasonographic techniques—mainly the introduction of transvaginal ultrasonography.[3,4] All these factors have dramatically changed the clinical picture of tubal pregnancy from a drastic and life-threatening disease to a more benign and less dangerous condition. In a series of 191 ectopic pregnancies that were diagnosed in our department during 1987 to 1989, 98% of patients were admitted because of clinically mild cases that needed no immediate emergency surgery. All had serum β-hCG determination before diagnosis and in 98% of patients at least one ultrasonographic examination was performed before diagnosis was established by laparoscopy or laparotomy. A ruptured tube was found in only 20% and active bleeding was found in only 10% of the patients (unpublished data).

It seems that the very early diagnosis of such pregnancies is also responsible, in part, for the increasing incidence because many of these early ectopic gestations remained undiagnosed in the past and were probably reabsorbed.

The dramatic change in the clinical picture of the disease and the drive to adjust the management to the new form of the disease, which is especially oriented to decrease the need for laparotomy and, as a direct result, to minimize the postoperative morbidity and recovery time, have recently stimulated many investigators to design various new and nonsurgical methods of treatment for early unruptured tubal pregnancies.[5]

The aim of the present analysis of these new modes of treatment is to reach some conclusions as to the indications, success rates, morbidity, and subsequent tubal patency of the various nonsurgical methods.

Medical treatment

Certain drugs are capable of acting on the trophoblastic cells and can arrest their growth and thus stop the development of the ectopic pregnancy, which is consequently absorbed. These can be introduced systematically or locally. Surgery can be avoided, and thus postoperative morbidity is minimized and recovery time is shortened. Moreover, the minimal surgical intervention, if any, in the pelvis minimizes the chance of adhesion formation and thus improves the future fertility rate.

Systemic administration

Methotrexate. Methotrexate is the prototype of the medical treatment of ectopic pregnancy, mostly because of its efficient action in stopping the development of the trophoblast. The drug inhibits the action of dihydrofolate reductase, which participates in the process of conversion of dihydrofolic acid to tetrahydrofolic acid. This process is essential to the synthesis of timin and purin, which take part in the synthesis of deoxyribonucleic acid (DNA). Methotrexate was introduced in 1956[6] and was the principal drug that was used in the treatment of gestational trophoblastic disease.

The first use of methotrexate in ectopic pregnancy was reported by Lathrop and Bowles[7] in 1963; they treated an abdominal pregnancy systemically with methotrexate and avoided a complicated operation.

Tanaka et al. in 1982[8] used methotrexate successfully in a patient with an interstitial pregnancy and demonstrated normal tubal patency afterward. A year later, the first attempt at treatment of a cervical pregnancy was reported by Farabow et al.[9] Although eventual surgery was not prevented, a definite decrease in pregnancy volume was reported, which probably ensured safer surgery.

The first series, although small, of ectopic pregnancies that were treated with systemic methotrexate was reported in the Japanese literature by Miatzaki et al.[10] in 1983. In eight patients surgery could be avoided. The author emphasizes the fact that the concentration of β-hCG at the time of admission is one of the major determinants of success.

Ory et al. in 1986[11] were the first to report in Western literature on six cases of unruptured tubal pregnancy that were treated with systemic methotrexate. In his small series, one patient required a laparotomy for intraperitoneal hemorrhage, and two others received blood transfusions. Of all the reported tubal pregnancies that were treated until now with systematic methotrexate, we found 118 such cases,[12-20] of which there were seven failures that required surgery—an incidence of 5.9% (Table I).

Of these seven failures, in two cases no details were given concerning pregnancy size, notice of fetal pulse, or β-hCG level at the time of admission.[10, 16] In the other five cases, β-hCG level was above 5000 mIU/ml and in four cases, fetal pulse was recorded by ultrasonography. In one patient active fimbrial bleeding was also reported.[12]

It seems that the key to the selection of suitable cases to ensure the maximum success rate is the establishment of solid criteria. In a review of the reports published until now, we found the following criteria to be important: (1) pregnancy diameter of <3 cm,[12-14, 17] (2) unruptured tube,[10-17] (3) no active bleeding,[10, 11, 13, 14, 17] (4) β-hCG serum level <1500 mIU/ml,[12] (5) no fetal pulse during ultrasonography,[12] and (6) less than 100 ml of blood in the pouch of Douglas.[11] The first three criteria define the early unruptured tubal pregnancy, which is mandatory for any nonsurgical treatment. The level of β-hCG and the identification of fetal heart

LFT, Liver function tests; *BMS*, bone marrow suppression.

beat by ultrasonography are additional necessary safeguards. The adoption of these criteria for selection is reducing the number of cases that are suitable for this type of management to only 12% to 32% of all ectopic pregnancies.[11, 17]

Methotrexate unfortunately has several side effects, which in rare instances can also be fatal.[21] In the majority of cases the side effects are dose-dependent. Gastrointestinal side effects, which are the most common, include stomatitis and diarrhea. Other side effects, such as bone marrow suppression, impaired liver function, dermatitis, and pleuritis were also reported. The total incidence of side effects among the patients who were treated with methotrexate for ectopic pregnancy is reported as 20% (Table II).

An interesting attempt to reduce the rate of side effects was made by Stovall et al.[17] who tried to individualize the dose of methotrexate to the dynamic decrease in β-hCG levels by reducing the daily dose of methotrexate, according to change in the β-hCG levels. With this method, only 20% of the patients received four doses of methotrexate (1 mg/kg/day), compared with most of the other protocols, which treated all the patients with four to five doses of methotrexate. Stovall et al.[17] succeeded in reducing the rate of side effects to 8.3% without changing the success rate (Table II). Other investigators tried to overcome the problem of side effects by concurrent administration of citrovorum factor.[11-15, 17-20]

The future patency of the affected tube and the eventual fertility is in fact the ultimate parameter with which to evaluate the actual effectiveness of each mode of therapy. This is not an easy task because the numbers of cases and series are small. However, most researchers who examined the subsequent tubal patency after the systematic use of methotrexate reported an incidence of 53% to 100%, with an average incidence of 71% (Table I). This figure compares quite satisfactorily with the incidence of patency for various surgical methods.[22]

Actinomycin D. Actinomycin D acts as a ribonucleic acid polymerase inhibitor by binding with double helical DNA and blocking the transcription of the DNA molecule. Actinomycin D is known to have less hepatic and renal toxicity than methotrexate.

The first and only successful case of systemic treatment with actinomycin D was reported by Altaras et al.[23] They treated a patient who was shown to have an interstitial pregnancy with 0.5 mg/day actinomycin D (intraveneously) for 5 days and demonstrated an immediate pattern of decreasing β-hCG levels and bilateral tubal patency several weeks later.

RU 486 (mifepristone). The introduction of RU 486 (mifepristone) as a chemical abortifacient for intrauterine pregnancies[24, 25] has led some researchers to the conclusion that it may also act on ectopic pregnancies. RU 486 is an antagonist for the synthesis of progesterone in the corpus luteum and by this means arrests trophoblastic development.[24, 25] The first case that was treated was accidental,[26] in the treatment of what was thought to be an intrauterine pregnancy, which was later found to be a tubal pregnancy that showed no response to treatment. Kenigsberg et al.[27] treated residual tubal pregnancy with 650 mg of RU 486 and no decreases in serum β-hCG level and progesterone were shown. This pregnancy was later terminated with systemic methotrexate treatment.

Local injection

In view of the high toxicity and the potential side effects of the drugs that are given systematically, investigators were searching for a direct way to introduce a small amount of the drug to the pregnancy site. Technical improvement of laparoscopy and transvaginal ultrasonographic techniques enabled some investigators

to administer local injections into the ectopic site and thus drastically reduce the dose of the drug required and avoid the potential side effects and the need for surgery.

Transvaginal ultrasonography

METHOTREXATE. Feichtinger and Kemeter[28] in 1987 were the first to use transvaginal ultrasonography for suction and injection of methotrexate into the tubal gestational sac of a patient who had undergone in vitro fertilization. Only 10 mg of methotrexate was used, which is about 5% of the usual systemic dose. The β-hCG level at the time of injection was 500 mIU/ml, and no fetal pulse was detected. With the same protocol, the same researchers recently reported[29] eight more cases that were treated by transvaginal ultrasonographic local injection of methotrexate and showed a success rate of 89%.

Robertson et al.[30] in 1987 reported a less successful experience with suction and injection of methotrexate with the use of transvaginal ultrasonography. They had to operate on five of nine patients who were previously treated by this method because of continuing development of adnexal masses and rising β-hCG levels.

Leeton and Davison[31] reported on their successful experience in the treatment of two cases of tubal pregnancy that were diagnosed early, before any symptoms appeared, in patients who had undergone in vitro fertilization. Fetal heart beat was demonstrated in the tube in both cases. Suction and transvaginal injection of 50 mg of methotrexate into the gestational site was performed and showed complete resolution of the tubal pregnancies.

POTASSIUM CHLORIDE. Robertson et al.[32] tried to avoid surgery in a complicated case of heterotopic pregnancy in a patient who had undergone in vitro fertilization, and they chose not to use methotrexate because of a concomitant intrauterine pregnancy. The locally injected 20% solution of potassium chloride was supposed to induce cardiac arrest of the ectopic fetus and thus cause absorption of the ectopic pregnancy. The injection was performed transabdominally, under ultrasonographic guidance, and was anticipated by suction of the content of the sac. This attempt proved successful, the ectopic pregnancy was terminated and absorbed, and the intrauterine pregnancy was saved. They treated two more patients with the same method, both of whom required a later laparotomy for rising β-hCG levels and development of an adnexal mass.

Timor-Tritsch et al.[33] in 1988 reported another successful case of vaginal injection of potassium chloride into a tubal pregnancy in which a fetal pulse was detected, and the absorption of the pregnancy content was achieved.

The main advantage of the use of potassium chloride as opposed to methotrexate is its relative lack of systemic side effects. Its main drawback, which may be responsible for failure in some cases, is that potassium chloride acts mainly on the fetal heart and causes asystole and fetal death. This drug has no effect on the trophoblastic tissue, which may continue to grow even without a developing fetus and thus induce rupture of the tube.

PROSTAGLANDINS. Ribic-Paucelj et al.[34] recently reported on their preliminary experience with ultrasonography for local injection of prostaglandin E_2 (PGE_2) for unruptured tubal pregnancy. Two patients were treated with this method; no effect on β-hCG levels was shown, and the patients required surgery later. Feichtinger and Kemeter,[29] in the same year, reported on a single case that was treated with transvaginal ultrasonographic local injection of PGE_2. Again no effect was shown in the β-hCG level, and laparotomy had to be performed to terminate the pregnancy. In addition, this patient experienced severe gastrointestinal discomfort, such as cramps and vomiting.

Analysis of these results seems to show that local injection of PGE_2 with the use of ultrasonography is less efficient in comparison with other drugs that are used in the same way.

Usually transvaginal ultrasonographic injection was exercised in patients who had undergone in vitro fertilization or in other patients who were at high risk of the development of ectopic pregnancy.[28, 31, 32] In the vast majority of the unruptured ectopic pregnancies, the diagnosis is not finally established by ultrasonography, and therefore laparoscopy is indispensable. In our series of 191 ectopic pregnancies, 70% underwent at least one transvaginal ultrasonographic examination, and ectopic pregnancy was definitely diagnosed by ultrasonography in only 7% (unpublished data).

A question still to be answered is whether the suction of the contents of the gestational sac or the injection of methotrexate, potassium chloride, or PGE_2 is the direct cause of success in these cases. A controlled, randomized study in which suction only or injection only is performed is needed to clear this dilemma.

Laparoscopy. The laparoscope is considered to be the principal means of diagnosis of ectopic pregnancy. In a recent study that was performed in our department and included 233 patients with suspected ectopic pregnancies, 198 (85%) underwent diagnostic laparoscopy with a 99% success rate in the diagnosis or ruling out of ectopic pregnancy.

The ability to diagnose most ectopic pregnancies and to treat them during the same procedure is an important advantage of laparoscopy over transvaginal ultrasonography. Another major advantage of laparoscopy is the ability to directly evaluate the size of the preg-

nancy, the tubal condition, and other pathologic conditions in the pelvis. In some selected cases, even minor surgical procedures such as lysis of adhesions or tubal sterilization can be performed. The advantages of combining the local injection under direct vision with the use of the laparoscope opened a new field of treatment for early, unruptured tubal pregnancy.

METHOTREXATE. We first reported a single, local injection of methotrexate with the use of the laparoscope in 1989.[35] Methotrexate in a dose of 12.5 mg was injected locally in 27 patients with unruptured tubal pregnancies. The criteria for selection were an unruptured tube, a pregnancy diameter of <3 cm, no active bleeding, and no additional pelvic pathologic conditions. These 27 patients represented 40% of all ectopic pregnancies that were diagnosed during the study period. Twenty-four (88%) patients needed no additional surgery, whereas three patients underwent surgery because of rising titers of β-hCG with or without abdominal pain. The use of local injection enabled us to reach high concentrations of methotrexate at the pregnancy site and to avoid the systemic route; thus, possible related side effects were eliminated. Subsequent tubal patency was evaluated with hystersalpingography in 21 patients 3 months later and showed a 90% tubal patency of the affected tube.[36]

A combination of local injection with a single systemic dose of 0.5 mg/kg of methotrexate was reported during the same year[37] in an attempt to lower the systemic effect. In this report, eight of 10 patients did not need surgery, and only one patient experienced stomatitis.

PROSTAGLANDINS. The effect of prostaglandins, especially that of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) on tubal function and on the corpus luteum, was recently reported.[38] It was found that $PGF_{2\alpha}$ causes increased tubal peristalsis and vasospasm of arteries in the mesosalpinx. It also showed that $PGF_{2\alpha}$ is a luteolytic agent that induces a decrease in progesterone production of the corpus luteum. This was tested by Lindblom et al.[39, 40] who injected $PGF_{2\alpha}$ (0.5 to 1.5 mg) locally into the tubal pregnancy and the corpus luteum with the laparoscope. In their small series, eight of nine patients did not require surgery. Lindblom et al. explained that the increased peristalsis of the tube caused tubal abortion of the pregnancy and that the vasospasm of the vessel prevented massive bleeding from the pregnancy site, and the luteolytic effect on the corpus luteum helped to lower hCG production.

Egarter et al.[40] used a combination of a local injection into the tube and corpus luteum of a slightly higher dosage of $PGF_{2\alpha}$ with systemic administration of PGE_2 in 18 patients and avoided surgery in 16. In their report, severe hemodynamic and cardiac side effects developed in three patients, one had massive pulmonary edema as a result of malignant hypertension and complete atrioventricular block, and the other had severe cardiac arrythmia. Those complications were explained by the massive absorption of the drug through the ovarian vasculature to the circulation. After these complications had occurred, they recommended a change in the protocol of treatment to an injection of estrogen (E_2) (instead of $PGF_{2\alpha}$) into the corpus luteum to induce a luteolytic effect.

The same research group[42] recently reported on a prospective multicenter study in which the new treatment of tubal pregnancy by means of local $PGF_{2\alpha}$ and systemic PGE_2 administration was compared with the usual surgical technique of eliminating the conceptus. Of 71 patients who were treated with prostaglandins, the method proved to be successful in 81%; 19% required surgical intervention later. The duration of hospitalization was significantly reduced in the prostaglandin group in comparison with the patients who were treated by primary surgery. In the prostaglandin group, only two of 24 subsequent hysterosalpingograms showed tubal occlusion after treatment, whereas occlusion was present in three of eight patients in the surgically treated group.

Another research group, with the original protocol of Lindblom et al.,[39] reported a 90% success rate with no side effects.[43] As in most other series with this type of therapy, the main concern is the selection of patients with emphasis on the size of the pregnancy and the initial β-hCG level. On hysterosalpingograms, tubal patency was shown to be similarly satisfactory and even better than in most other series (Table III).

An alternative to the use of prostaglandins was offered by Lang et al.[44] who performed a randomized study with laparoscopic local injection of hyperosmolar glucose in nine patients who had unruptured tubal pregnancies. They used local injection of $PGF_{2\alpha}$ combined with systemic PGE_2 in another nine patients. Better results, including fewer side effects, were noticed with the former method, and there was no need for subsequent surgery. In the prostaglandin group that required additional surgery, there was one failure and six patients reported severe abdominal pain, which was probably a result of the prostaglandin effect (Table III).

Expectant management

Ectopic pregnancy can resolve spontaneously and express only mild clinical signs or no clinical signs at all.[45] Arias Stella[46] in 1954 reported specific histologic changes in the endometrium as a result of the hCG effect, when no intrauterine pregnancy was present. In a few of these cases the source of hCG was an ectopic pregnancy, which resolved spontaneously.

Ohel et al.[47] described a patient who had minimal

clinical signs and who was diagnosed accidently as having a tubal pregnancy during laparoscopy. The pregnancy was later found in the pouch of Douglas, and there was no need for further treatment.

The fact that a considerable number of ectopic pregnancies that are diagnosed today are in a very early stage because of modern means of diagnosis, the high index of suspicion, and the fact that many of these pregnancies would have resolved spontaneously with no additional therapy form the basis of expectant management.

In 1955 Lund[48] was the first to try such an expectant management in ectopic pregnancy, and he attempted to answer two major questions: (1) What is the natural course of events and the clinical pattern of an early ectopic pregnancy when it is left untouched? and (2) When no surgery takes place and the pregnancy is reabsorbed, is there any effect on future fertility?

The diagnosis of ectopic pregnancy was based on clinical and physical examination, measurement of urinary hCG level with the Friedman technique, and curettage. Of 119 patients who entered the study, 57% did not need surgery and recovered with bed rest alone. No maternal mortality was reported, although many emergency operations were performed in the remainder of the group. In 46% of the patients who did not have surgery, an intrauterine pregnancy was reported, and in 15% ectopic pregnancy recurred.

A study of 600 Chinese women who were treated with traditional Chinese drugs or expectant management alone, was reported in the Chinese literature by Wone[49] in 1977. It is difficult to evaluate this study because few details were given concerning diagnosis and follow-up, but two cases of maternal death were reported.

Mashiach et al.[50] in 1982 reported for the first time, five patients in whom tubal pregnancy was treated with only expectant management. In three patients the diagnosis was established by laparoscopy. The criteria for selection were hemodynamic stability, β-hCG serum level <250 mIU/ml (or in a decreasing pattern), and pregnancy diameter <2 cm. One patient (20%) required a laparotomy because of abdominal pain and rising titers of β-hCG.

This series was further extended by the same research group[51] who reported on 12 of 14 patients in whom diagnoses were confirmed at laparoscopy. Only three patients required further surgery. Recently, several authors described small series of ectopic pregnancies that were treated with expectant management (Table IV). In about 60% of the 61 cases that have been reported so far, definite diagnoses were established by means of laparoscopy. The subsequent reported average success rate was 82% (range 71% to 100%). Subsequent tubal patency ranged from 70% to 100% and was no different from reports on tubal patency after other modes of therapy (Tables I and III).[22] Fertility was also covered in a few of these reports (Table IV) and showed a somewhat lower incidence of intrauterine pregnancies compared with a few recent reports of conservative surgery for tubal pregnancy.[52, 53]

There is no doubt that a certain number of ectopic pregnancies are being "overtreated" these days. Al-

though we have sophisticated means of early diagnosis, it is still very difficult to determine safe and effective criteria at diagnosis, which will help to differentiate between those pregnancies that are destined to be absorbed spontaneously and those that will continue to grow and finally rupture the tube. Reliance on the clinical presentation alone (as was done by Lund[48]) will result in large numbers of emergency operations and irreversible damage to about 50% of patients. Use of β-hCG levels will postpone treatment by at least 24 to 48 hours,[14] and more than that, a decrease in amounts of β-hCG is not always a guarantee of complete resolution.[54]

We think that expectant management is appropriate in a very small number of patients, who meet the strict criteria of minimal clinical complaints, a definite pattern of decreasing β-hCG levels, and laparoscopic confirmation of a small, unruptured, and nonbleeding tubal pregnancy.

Comment

The clinical picture of ectopic pregnancy has dramatically changed in recent years from an emergency situation and a life-threatening condition, in most cases, to a much more benign condition with milder presentation. Because patients are usually in excellent clinical condition and hemodynamically stable, many investigators were able to successfully treat many of them with new and less invasive procedures and to achieve more than satisfactory results. In an analysis of these methods, we found that the success rates of most of them are practically equal (80% to 90%) when compared with those few reports of expectant management alone. It seems that local injection under ultrasonographic control is an exception that shows somewhat less promising results. This is probably because of suboptimal visualization of the gestational sac and thus reduced accuracy in localization of the injection site.

The selection criteria that were used by most investigators including small-sized pregnancies, low β-hCG levels, and the absence of fetal pulse, probably mean that many of these ectopic gestations were nonviable and would have resolved spontaneously regardless of the method of treatment used.

The main question that remains to be answered is how to determine, during the evaluation of a case of ectopic pregnancy, whether it is growing or destined to resolve spontaneously. We believe that at least two consecutive β-hCG determinations are needed to establish a rising trend before any treatment is started. Expectant management is probably the treatment of choice when no such trend is evident. However, when such a rise in β-hCG level is found, a prospective randomized study that compares the various nonsurgical measures may show which treatment modality is the safest and most efficient.

We thank Anji Agajany and Jane Geva for their invaluable assistance in the preparation of the manuscript.

Serum levels of inhibin in maternal and umbilical blood during pregnancy

Toru Tabei, MD,[a] Kazuhiko Ochiai, MD,[b] Yoshiteru Terashima, MD,[b] and Naoki Takanashi, PhD[c]

Kawagoe and Tokyo, Japan

Inhibin levels were measured by a double antibody heterologous radioimmunoassay in the peripheral serum of 75 pregnant women throughout gestation and in serum from the umbilical vein and artery, which was obtained at the time of delivery. For reference, samples were obtained from 20 nonpregnant women in the early (days 0 to 3), mid (days 4 to 8), and late (days 9 to 14) luteal or follicular phase. Maternal serum levels of inhibin (mean ± SEM) in early (6 to 12 weeks) gestation (36.4 ± 2.6 U/ml, $n = 36$) were significantly ($p < 0.01$) higher than those in serum from nonpregnant women in the mid (23.9 ± 2.5 U/ml, $n = 19$) or late (11.3 ± 0.6 U/ml, $n = 19$) luteal phase. Inhibin levels in maternal serum fell to 15.9 ± 1.4 U/ml ($n = 24$) in mid (14 to 20 weeks) gestation and then gradually increased during late (21 to 40 weeks) gestation to peak levels of 49.4 ± 5.1 U/ml ($n = 9$) at 36 to 37 weeks. Inhibin levels declined in parallel with human chorionic gonadotropin concentrations during the first trimester ($r = 0.587$ at $p < 0.01$). Significant positive correlations ($p < 0.001$) were observed between serum levels of inhibin and 17β-estradiol ($r = 0.560$), progesterone ($r = 0.648$), and human placental lactogen ($r = 0.715$) during mid and late (20 to 40 weeks) gestation. Inhibin levels in umbilical vein serum (38.5 ± 1.3 U/ml, $n = 5$) were not different from those in umbilical artery serum (39.4 ± 3.6 U/ml) but were significantly ($p < 0.01$) lower than those in maternal serum (50.9 ± 5.3 U/ml), which was obtained at the time of delivery. By day 5 of puerperium, serum levels of inhibin in the maternal vein were extremely low (2.3 ± 0.1 U/ml, $n = 7$); these levels were nearly one fifth lower than follicular phase levels of 10.9 ± 3.4 U/ml ($n = 38$). We propose that maternal inhibin in early gestation is secreted from the corpus luteum of pregnancy but that increasing inhibin levels during mid and late gestation result from inhibin that is produced by the placenta. The lack of an umbilical arterial-venous gradient for inhibin and the higher levels of inhibin in maternal serum argue against a fetal source of inhibin in the maternal circulation. The physiologic function of inhibin that is produced by the corpus luteum and by the placenta remains to be determined. (Am J Obstet Gynecol 1991;164:896-900.)

Key words: Inhibin, pregnancy, placenta, umbilical blood

Inhibin, a glycoprotein hormone that is secreted by the ovaries and testes, is a regulator of pituitary follicle-stimulating hormone secretion.[1, 2] The molecule has been purified and characterized as a heterodimeric protein with α- and β-subunits.[3] A specific and sensitive heterologous radioimmunoassay for the measurement of the circulating serum levels of human inhibin has been developed,[4] and results during normal menstrual cycle,[5] in early normal pregnancy,[6] and in three pregnancies in women with ovarian failure throughout gestation[7] have been reported. In normal women inhibin levels rise during the luteal phase in parallel with progesterone levels,[5] which suggests that inhibin is produced by the corpus luteum.

Recently, inhibin bioactivity and immunoactivity have been demonstrated in the human placenta, which suggests that inhibin is produced by the human placenta during pregnancy.[7-10] Inhibin gene expression[11] and messenger ribonucleic acid (mRNA) for the α-subunit of inhibin[12] have also been demonstrated in the human placenta. In addition, elevated circulating immunoactive inhibin levels were found in women with complete hydatidiform mole during early pregnancy.[13]

There are presently no reports that describe the

physiologic characteristics of inhibin secretion throughout pregnancy. Therefore we measured the concentrations of circulating inhibin in maternal serum throughout gestation and in umbilical vein and artery serum that was obtained at the time of delivery.

We have also assessed the relationship between levels of inhibin in maternal serum and those of 17β-estradiol, progesterone, human placental lactogen, and human chorionic gonadotropin, all of which are produced by the human placenta during gestation.

Patients and methods

Serum samples were obtained on 158 occasions from the peripheral vein of 75 pregnant women throughout gestation (6 to 40 weeks), from the umbilical vein and artery of five pregnant women at the time of delivery, and on 87 occasions from the peripheral vein of 20 nonpregnant women with normal ovulatory cycles.

The menstrual cycle of nonpregnant women was divided into six phases: early (day 14 to day 9), mid (day 8 to day 4), and late (day 3 to day 0) follicular phases and early (day 0 to day 3), mid (day 4 to day 8), and late (day 9 to day 14) luteal phases. The day of ovulation was designated as day 0 from charts of daily basal body temperature. Gestational age of pregnant women was calculated from the last menstrual period and/or reevaluated by ultrasonographic findings. Serum was frozen and stored for measurement of inhibin, 17β-estradiol, progesterone, human placental lactogen and human chorionic gonadotropin by radioimmunoassay or enzyme immunoassay.

Serum levels of inhibin were measured by a double antibody heterologous radioimmunoassay with iodine 125-labeled purified 31 kd inhibin from bovine follicular fluid and rabbit antiserum to 31 kd bovine inhibin, which was supplied by Drs. D.M. DeKretser and D.M. Robertson of Monash University in Australia. Serum samples (0.1 ml) were assayed in duplicate. The assay standard was World Health Organization porcine inhibin. This standard was assigned a unitage of 2000 U per ampule by the World Health Organization working group. Parallelism was observed between dose-response lines of the World Health Organization inhibin standard, human serum, and human follicular fluid. The specific binding of ^{125}I-inhibin (bound/total; B/T) was 35% in the radioimmunoassay. The minimum detectable dose was 2 U/ml with a 95% confidence interval. The median effective dose was 18 U/ml. The intraassay and interassay coefficients of variation were 3.8% and 7.8%, at 17.3 U/ml, respectively.

Serum concentrations of human chorionic gonadotropin were determined by enzyme immunoassay with reagents that were supplied by Takeda Pharmaceutical Co., Osaka.[14] Serum concentrations of 17β-estradiol,[15] progesterone,[16] and human placental lactogen[17] were measured by radioimmunoassay with reagents that were supplied by Japan D.P.C. Corp., Tokyo, and Pharmacia, Uppsala.

Statistical analyses were performed by comparison of the date with Student's t test, one-way analysis of variance, and linear regression analysis. Groups were considered to be significantly different at a level of $p < 0.01$ or $p < 0.001$. Data were expressed as the mean ± SEM.

Results

Serum levels of inhibin (mean ± standard error of the mean, U/ml) throughout the normal menstrual cycle were similar during the early (9.0 ± 0.4 U/ml, $n = 11$), mid (11.6 ± 1.0 U/ml, $n = 16$), and late (11.1 ± 0.6 U/ml, $n = 11$) follicular phases. Serum levels of inhibin were increased during the early luteal phase (16.5 ± 3.8 U/ml, $n = 8$), reached maximum levels of 23.9 ± 2.5 U/ml ($n = 19$) in the mid luteal phase, and declined in the late luteal phase to 11.3 ± 0.6 U/ml ($n = 19$). The serum levels of inhibin in early (6 to 12 weeks) gestation (36.4 ± 2.6 U/ml, $n = 36$) were significantly ($p < 0.01$) higher than those in the mid and late luteal phases of nonpregnant women.

Circulating maternal levels of inhibin at weekly intervals throughout pregnancy are compared with those of 17β-estradiol, progesterone, human placental lactogen, and human chorionic gonadotropin throughout gestation in Fig. 1. Fig. 1, *a*, shows that serum levels of inhibin were elevated during early (6 to 19 weeks) gestation with peak levels of 45.1 ± 5.2 U/ml ($n = 12$) at 8 to 9 weeks, declined to lower levels (15.9 ± 1.4 U/ml, $n = 24$) in mid (14 to 20 weeks) gestation, and then progressively increased with gestational age during mid and late (20 to 40 weeks) gestation to peak levels of 49.4 ± 5.1 U/ml ($n = 9$) at 36 to 37 weeks. The pattern of increase in serum inhibin during mid to late gestation was similar to that of 17β-estradiol (Fig. 1, *b*), progesterone (Fig. 1, *b*) and human placental lactogen (Fig. 1, *c*) but differed from that of human chorionic gonadotropin (Fig. 1, *c*). Significant positive correlations were observed between circulating inhibin and 17β-estradiol ($r = 0.560$ at $p < 0.001$, $n = 103$) (Fig. 2), progesterone ($r = 0.648$ at $p < 0.001$, $n = 104$) (Fig. 3), and human placental lactogen ($r = 0.715$ at $p < 0.01$, $n = 103$) (Fig. 4) during mid and late gestation. Although no significant correlation ($r = 0.329$, $n = 103$) was found between inhibin and human chorionic gonadotropin concentrations between 20 and 40 weeks, a striking correlation was observed in the period of 6 to 20 weeks' gestation ($r = 0.587$ at $p < 0.001$, $n = 56$).

The levels of inhibin (mean ± SEM, U/ml) in maternal vein serum samples that were obtained from five pregnant women at the time of delivery (50.9 ± 5.3

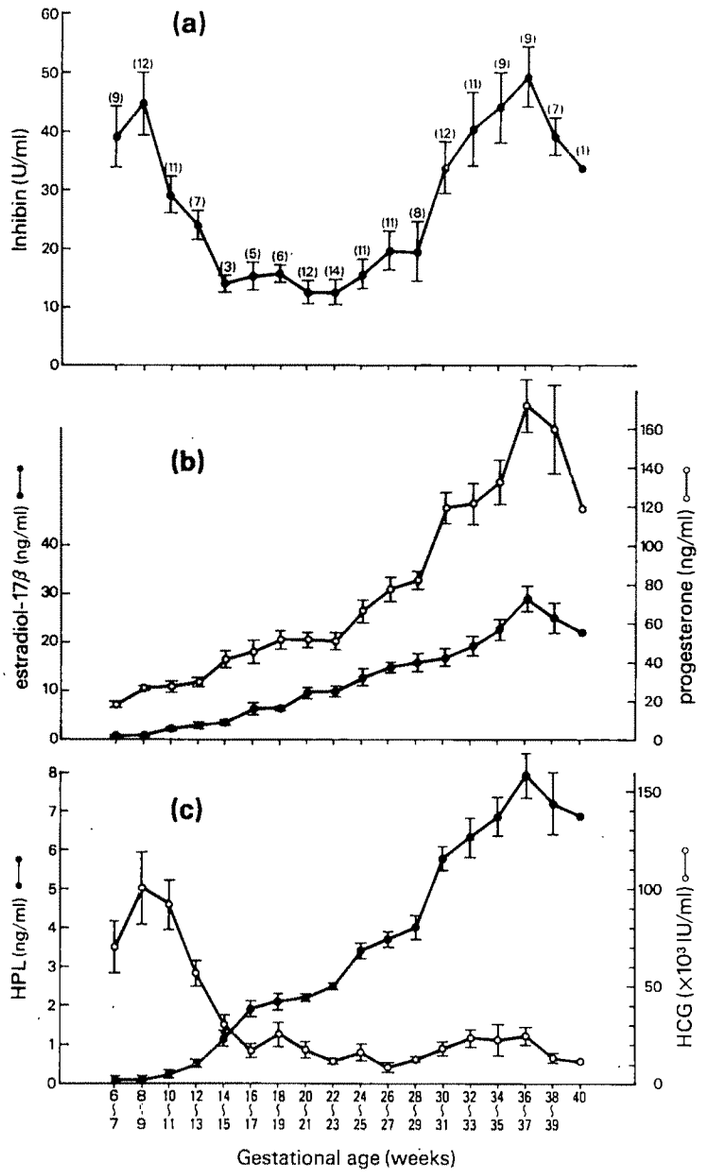

Fig. 1. Serum levels (mean ± SEM) of inhibin (units per milliliter), 17β-estradiol (nanograms per milliliter), progesterone (nanograms per milliliter), human placental lactogen *(HPL)* (nanograms per milliliter), and human chorionic gonadotropin *(HCG)* ($\times 10^3$ IU/ml), which were obtained from 75 pregnant women throughout gestation (6 to 40 weeks). Total number of serum samples was 158. *Values in parentheses* refer to numbers of serum samples for measurement.

U/ml) were significantly ($p < 0.01$) higher than those in samples that were obtained from the umbilical vein (38.5 ± 1.3 U/ml) and the umbilical artery (39.4 ± 3.6 U/ml). There was no significant ($p < 0.01$) difference between the umbilical venous and umbilical arterial concentrations. In addition, the serum levels of inhibin in maternal vein serum, which was obtained from seven mothers at day 5 of puerperium, were extremely low (2.3 ± 0.1 U/ml). The levels were approximately one fourth less than those in normal women during the follicular phase, 10.9 ± 3.4 U/ml ($n = 38$).

Comment

This study demonstrates that circulating levels of immunoactive inhibin are elevated during early gestation, gradually decline to lower levels in mid gestation, and then increase with gestational age to peak levels at 36 to 37 weeks. This pattern of increase in serum inhibin

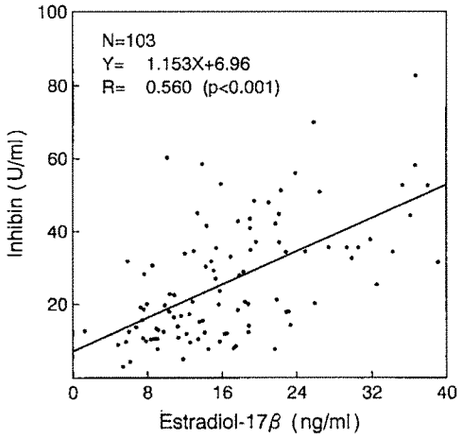

Fig. 2. Relation between serum levels of inhibin and those of 17β-estradiol during mid and late gestation (20 to 40 weeks); $r = 0.560$ at $p < 0.001$.

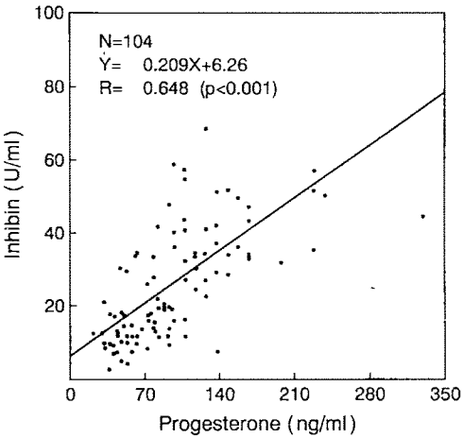

Fig. 3. Relation between serum levels of inhibin and those of progesterone during mid and late gestation (20 to 40 weeks); $r = 0.648$ at $p < 0.001$.

during mid and late gestation is similar to the patterns of increase of 17β-estradiol, progesterone, and human placental lactogen, all of which are produced by the human placenta. By contrast, inhibin levels paralleled those of human chorionic gonadotropin in early gestation.

Previous studies have demonstrated biologic and immunologic activity of inhibin[8-10] and inhibin α-subunit mRNA[12] in the human placenta. In addition, elevated levels of inhibin throughout gestation were reported in three pregnant women without ovarian tissue.[7] These data and our present findings suggest that the placenta is an important source of inhibin during mid and late pregnancy. The positive correlation between inhibin levels and the concentration of 17β-estradiol, progesterone, and human placental lactogen in mid to late pregnancy suggests that a common mechanism governs the synthesis and secretion of these placental steroids and proteins. The concentration of mRNA per cell for human placental lactogen is believed to remain relatively constant during pregnancy,[18] which suggests that the increase in total placental human placental lactogen mRNA[19] is due to an increase in the number of syncytial cells that express the human placental lactogen gene rather than to a hormonal factor that regulates human placental lactogen mRNA. A similar mechanism may explain the concomitant increase of inhibin secretion. However, a paracrine effect of inhibin cannot be excluded.

A fetal source of inhibin is unlikely because of the higher levels in maternal serum than those in umbilical blood serum that was obtained at the time of delivery and because of the absence of an umbilical venous/arterial difference.

On the other hand, the source of elevated inhibin

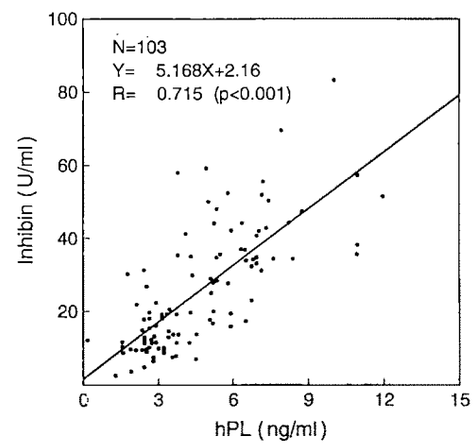

Fig. 4. Relation between serum levels of inhibin and those of human placental lactogen *(hPL)* during mid and late gestation (20 to 40 weeks); $r = 0.715$ at $p < 0.001$.

during early pregnancy may be from the maternal corpus luteum or the placenta. The gradual decrease in inhibin levels, which paralleled that of human chorionic gonadotropin concentrations during early pregnancy in normal pregnant women, together with the absence of this pattern in pregnant women with ovarian failure and oocyte transfer,[7] suggests that the ovary is the source of high inhibin levels in maternal serum during the first trimester. Inhibin α-subunit mRNA has been found in the corpora lutea of primates,[20] and ablation of the corpus luteum leads to an abrupt decline in circulating inhibin levels.[21] The finding that a gonadotropin releasing hormone antagonist abruptly reduced inhibin secretion in the luteal phase of nonhuman

primates[22] indicates that pituitary gonadotropins regulate the secretion of inhibin by the corpus luteum. Thus it is likely that human chorionic gonadotropin also stimulates inhibin production through an action on the ovary during pregnancy. The ovary, however, is not the only major source of inhibin production in early pregnancy since inhibin was present in the serum of three pregnant women who had no ovarian function.[7] Thus further studies are required to define the source and regulation of the elevated circulating inhibin during pregnancy.

A significant difference between bioactive and immunoactive inhibin in the human placenta and ovaries[9] may reflect the secretion of isoforms of inhibin with variable biologic activities.[23] A bioactive/immunoactive difference was also observed in human serum.[24] We have not yet examined the bioactivities of inhibin that is produced during pregnancy. The physiologic role of placental inhibin is presently unknown. Potential functions of placental inhibin may include the endocrine control of gonadotropin secretion by the mother or fetus or the paracrine actions within the fetoplacental unit.

Since inhibin is secreted into the maternal circulation by the human placenta in parallel with other placental hormones during mid and late gestation, measurement of this substance may serve as an index of placental function.

We acknowledge Drs. Philip Troen and Stephen J. Winters of the University of Pittsburgh for their kind review of the manuscript and valuable advice, and Drs. D.M. DeKretser and D.M. Robertson of the University of Monash, Australia, for the gift of inhibin radioimmunoassay reagents.

Restriction fragment length polymorphism analysis to study the genetic origin of complete hydatidiform mole

Tsang-Ming Ko, MD, Chang-Yao Hsieh, MD, Hong-Nerng Ho, MD, Fon-Jou Hsieh, MD, and Tzu-Yao Lee, MD

Taipei, Taiwan, Republic of China

To determine the genetic origin of the complete hydatidiform mole, 20 abnormal pregnancies were studied with restriction fragment length polymorphism with five genomic probes: EJ 6.6, β-globin gene, 3′α-hypervariable region, J-Bir, and St14. In the 12 cases of molar pregnancy, pure paternal origin was proved in 11 cases, but both maternal and paternal inheritance were shown in only one case. In the cases with pure paternal origin, all of the restriction fragment length polymorphisms were homozygous, although those of the fathers were heterozygous at 15 loci. In the four cases that mimicked hydatidiform mole but were diagnosed as hydropic change of villi, both paternal and maternal inheritance were noted. In the four pregnancies with blighted ovum, both paternal and maternal inheritance were shown in three cases; and in one case with a balanced translocation between chromosomes 13 and 14, only paternal inheritance was noted. This study showed that most of the complete hydatidiform moles were caused by fertilization of an empty egg by a duplicated haploid sperm, but rare exceptions may exist. (Am J Obstet Gynecol 1991;164:901-6.)

Key words: Complete hydatidiform mole, restriction fragment length polymorphism, genetic origin

Complete hydatidiform mole is an abnormal pregnancy that is characterized by swollen chorionic villi and trophoblastic hyperplasia, and it has a propensity to malignancy.[1] Most of the cases of complete hydatidiform mole have 46,XX chromosome complement, and only a few have 46,XY. The genetic origin of the complete hydatidiform mole has been studied by means of chromosome heteromorphism and/or analysis of polymorphic enzymes of the molar tissue and the parental blood.[2-9] Most of the 46,XX moles are derived from fertilization of an "empty" egg by a duplicated haploid sperm,[2, 4, 8, 9] whereas the 46,XY moles are caused by dispermy.[3, 5, 6] However, chromosome heteromorphism study might be subject to technical variation, and the reliability of subjective assessment of the visible chromosome heteromorphism has been questioned.[10] Evaluation by other means would be useful for further confirmation of the previous observation.

The recent advance in molecular biology has enabled us to use deoxyribonucleic acid (DNA) markers to trace the parental origin of many conditions, such as Down syndrome, Edwards syndrome, and the issue of paternity.[11, 12] In genomic DNA, one mutation occurs in about every 300 to 500 nucleotides. Some of the mutations affect the recognition site of certain restriction enzymes, which generates two-allelic restriction fragment length polymorphism when the DNA is digested with a particular enzyme. In addition, there are many regions in the genome, which are composed of repeating sequences that are arranged in tandem and that result in highly polymorphic multiallelic restriction fragment length polymorphisms because of the insertion-deletion of these sequences. These site and length polymorphisms are useful and reliable markers in linkage analysis for the prenatal diagnosis of single-gene disorders[13-15] and for the identification of genetic origin of many conditions.[11, 12]

Taiwan has a relatively high incidence of complete hydatidiform mole.[16] Recently, it was estimated that about 1 in 500 pregnancies turns out to be complete hydatidiform mole. The mechanisms of complete hydatidiform mole development are still not completely clear. Although, in most cases, the genetic origin of complete hydatidiform mole has been shown to be paternal by chromosome heteromorphism study, further confirmation by restriction fragment length polymorphism analysis will be very valuable. For this purpose, we have collected 12 histologically confirmed cases of complete hydatidiform mole and 8 cases of other pregnancy wastage; we have studied five restriction fragment length polymorphisms of these conceptions with genomic probes from three chromosomes.

Patients and methods

Sixteen conceptuses with grossly vesicular change of the chorionic villi and four conceptuses with normal-appearing chorionic villi were collected in this study. All of the conceptus products were obtained aseptically and were usually divided into three parts. The first part was fixed in formalin-alcohol for histologic examination; the second part was set up in tissue culture for cytogenetic analysis; and the third part was directly extracted for DNA for restriction fragment length polymorphism study.

Family 1 requires some description. A 29-year-old woman, gravida 5, para 2, came to our hospital at 15 weeks' gestation; she complained of intermittent vaginal spotting that had lasted for about 2 months. Physical examination showed hypertension (186/110 mm Hg), lower-leg edema, and a large-for-date uterus at umbilical level. Ultrasonographic examination showed a normal-appearing fetus with active fetal heart motion. The biparietal diameter of the fetus was 3.1 cm, which is compatible with the gestational age. A normal placenta was located at the anterior uterine wall. However, more than half of the intrauterine volume was occupied by a complex echogenic and echolucent mass that was compatible with a molar pregnancy. The placenta and the vesicular tissues were clearly separable. Because of severe hypertension and the ultrasonographic findings, termination of the pregnancy was advised. While the patient was under epidural anesthesia and continuous ultrasonic guidance, about 660 gm of vesicular tissue was suctioned out. The fetus and the placenta were evacuated in fragments. The fetus measured about 10 cm from crown to feet and weighed about 20 gm. The placenta measured about 10 × 6 × 0.5 cm and weighed about 22 gm. No vesicular change was noted in the placenta. The molar tissue and placenta fragments were obtained for both cytogenetic and DNA analysis.

For tissue culture, the decidual tissues were removed under a dissecting microscope. The gestational products were then treated with trypsin-collagenase to yield small tissue fragments, which were cultured with Chang's medium in an incubator at a temperature of 37° C with 5% carbon dioxide. Routine G-banding was used in the determination of karyotypes. In a few cases in which cytogenetic study failed or was not done, determination of the sex of the conceptus was performed by dot hybridization with Y-specific probe pY3.4.[17]

For restriction fragment length polymorphism analysis, in addition to the gestational tissue, white blood cells from both parents were also needed. From each parent, 10 ml of venous blood was obtained and anticoagulated with ethylenediaminetetraacetic acid. The buffy coat was separated for DNA extraction, and the maternal plasma was used for quantitation of the β-subunit of human chorionic gonadotropin.

Methods for DNA extraction were described previously.[14] Briefly, the molar and villous tissues were pulverized after they had been frozen in liquid nitrogen. The tissue powder and buffy coat were treated with lysing buffer, followed by ribonuclease A and then proteinase K digestion. DNA was purified by phenol-chloroform extraction, extensive dialysis, and ethanol precipitation.

Five genomic probes, two (EJ 6.6 and β-globin gene) from chromosome 11,[14] one (3′ hypervariable region of α-globin gene [3′α-HVR]) from chromosome 16,[18] and two (J-Bir and St14) from the X chromosome (the former from the short arm and the latter from the long arm),[19, 20] were used for restriction fragment length polymorphism study (Table I). β-Globin gene and J-Bir probes detected two-allelic polymorphisms, and the other probes detected multiallelic polymorphisms.

For each restriction fragment length polymorphism study, 5 μg genomic DNA was digested with 15 to 20 U restriction enzyme (Boehringer Mannheim, Penzberg, Federal Republic of Germany; Bethesda Research Laboratories, Gaithersburg, Md., and Toyobo Co., Ltd., Osaka, Japan) under the conditions recommended by the manufacturers. The DNA fragments were size fractionated by 0.8% agarose gel electrophoresis and then transferred to nylon filter (Zetabind, Cuno Inc., Meriden, Conn.) by Southern blotting.[21] After baking in a vacuum, the filter was prehybridized and then hybridized with a phosphorus 32-labeled radioactive probe, which was prepared by nick-translation or random-primer method.[22, 23] The filter was washed under stringent conditions and then autoradiographed for 3 to 7 days at a temperature of −70° C as described previously.[14] For the two-allelic restriction fragment length polymorphisms, (+) was designated for the presence of the polymorphic site and (−) was designated for the absence of the site. For the multiallelic restriction fragment length polymorphisms Arabic numerals were used in each family for distinction of the different alleles; the same numeral from different families did not necessarily represent the same allele. The maternal β-human chorionic gonadotropin levels were

quantitated by enzyme-linked immunoassay (Abbott Laboratories, Chicago).

Results

In the 16 cases with grossly swollen chorionic villi, 11 were diagnosed as complete hydatidiform mole, one as invasive mole (family 6), and the other four as hydropic change of villi by histologic conditions. Family 1 had twin pregnancy with one twin that developed to complete hydatidiform mole.

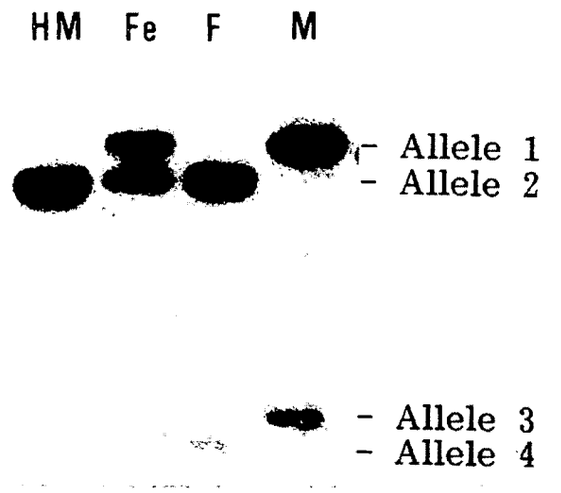

Fig. 3. Autoradiograph of DNA digestion with *Bgl* II and hybridization with probe 3′α-HVR in family 1. *Fe*, Fetus; other abbreviations as in Fig. 1 legend.

The results of cytogenetic study, β-human chorionic gonadotropin quantitation, restriction fragment length polymorphism analysis, and histologic study of the whole series are summarized in Table II. In the 12 confirmed cases of molar pregnancy, 11 were 46,XX; however, cytogenetic study was not done in family 5, but DNA dot hybridization showed absence of the Y chromosome.

Of the 12 cases of molar pregnancy, 11 (families 1 to 11) originated from the paternal side only as shown by restriction fragment length polymorphism (Table II, Figs. 1 to 5). All of the loci in molar tissue were homozygous, although 15 loci in the fathers were heterozygous. In family 12, the mole had both paternal and maternal complements as revealed by 3′α-HVR and St14 probes. In addition, restriction fragment length polymorphism at EJ 6.6 was also heterozygous, which is consistent with the paternal and maternal inheritance. The maternal β-human chorionic gonadotropin level was also highly elevated. After suction curettage, the patient had an uneventful course and conceived again about 1 year later.

In contrast to the first 11 cases of molar pregnancy, the four conceptions (families 13 to 16) that mimicked complete hydatidiform mole in gross appearance but were diagnosed as hydropic change of chorionic villi by histologic evaluation showed both paternal and maternal inheritance. In the other four pregnancies, which were clinically diagnosed as blighted ovum, both paternal and maternal inheritance were shown in three

cases (families 18 to 20). However, in case 17, cytogenetic study showed a balanced translocation between chromosomes 13 and 14, (45,XX,-13,-14,+t[13q,14q]); whereas the karyotypes of the peripheral blood in both parents were normal. Restriction fragment length polymorphism analysis showed pure paternal inheritance at the β-globin gene and 3′α-HVR loci. In addition, at the latter locus, the father was heterozygous and the conceptus was homozygous.

Comment

Restriction fragment length polymorphism analysis is very useful for tracing the genetic origin of many conditions.[11-15] In this study, 11 (92%) of the 12 cases of molar pregnancy inherited the genetic materials only from the paternal side; no maternal genome contributed to the conception products. This finding suggested that complete hydatidiform mole might originate from an empty egg that is fertilized by several mechanisms: (1) by two haploid sperm; (2) by a diploid sperm because of first meiosis failure; (3) by a diploid sperm because of second meiosis failure; and (4) by a haploid sperm, which then duplicates to produce a diploid chromosome complement. In this study, all of the restriction fragment length polymorphisms in the molar tissue were homozygous, even though 15 loci in the fathers were heterozygous (Table II). This fact does not favor the mechanism of fertilization by two haploid sperm or by a diploid sperm as a result of first meiosis failure. On the other hand, the three autosomal genomic probes, EJ 6.6, β-globin gene, and 3′α-HVR, are located at the terminal portions of chromosomes 11 and 16, respectively (Table I)[24]; hence DNA recombinations are very likely to occur during meiosis, and heterozygosity at some of these restriction fragment length polymorphisms is expected to be found in a diploid sperm as a result of second meiosis failure. However, no heterozygous restriction fragment length polymorphisms were detected in the first 11 cases of molar pregnancy. Hence the mechanism of fertilization of an empty egg by a haploid sperm, which then duplicates without cytokinesis to restore diploid number, seems most compatible with our observations and other previous reports.[2,4,8,9] Recently, Litt et al.[25] with probes for three highly polymorphic, variable-number tandem-repeat loci, also demonstrated homozygosity of complete hydatidiform mole. Saji et al.[26] with a minisatellite DNA probe, confirmed the androgenesis of complete hydatidiform mole. In mouse experiments the paternal genetic materials were found to be responsible for the growth of trophoblast, whereas the maternal genetic materials are needed for proper embryo development.[27,28] This animal model could explain the association of complete hydatidiform mole with pure androgenetic inheritance. However, in case 12, both maternal and paternal inheritance were noted as revealed by 3′α-HVR and St14 probes (Table II). The maternal β-human chorionic gonadotropin level and the cytogenetic study, gross appearance, and histologic evaluation of the conceptus were typical for a diagnosis of complete hydatidiform mole. The mechanism of maternal contribution to the genesis of complete hydatidiform mole needs further investigation.

In other types of pregnancy wastages, such as hy-

dropic change of villi, which mimicks complete hydatidiform mole and blighted ovum, both maternal and paternal inheritance were demonstrated in seven of the eight cases that were collected. In case 18 with 45,X, the only X chromosome was from the paternal side, as revealed by the St14 probe. However, in case 17 with a diagnosis of blighted ovum and a histologic confirmation of chorionic villi, only paternal genetic materials were found as shown by the β-globin gene and 3′α-HVR probes (Table II). Interestingly, the cytogenetic study of the chorionic villi revealed balanced translocation between chromosomes 13 and 14, whereas the karyotypes from the peripheral blood of both parents were normal. Because of the translocation, the androgenetic mechanism does not seem to arise from duplication of a haploid sperm. Whatever the cause, the outcome of the conception seemed to be influenced by an interaction of the chromosomal translocation and the androgenetic process. With an earlier diagnosis and termination of pregnancy wastage because of the widespread use of ultrasonic scanning in early gestation, it is possible that some conceptions that are destined to become hydatidiform moles can be terminated before typical manifestations develop.

In conclusion, the restriction fragment length polymorphism analysis of complete hydatidiform mole and of the parents confirms that most cases of complete hydatidiform mole are caused by the fertilization of an empty egg by a haploid sperm, which duplicates to restore a diploid karyotype. However, in rare instances, complete hydatidiform mole may have maternal genetic contribution, and in some pregnancy wastages, pure adrogenetic inheritance may be found.

The β-globin gene, 3′α-HVR, J-Bir, St14, and pY3.4 probes were provided by Drs. Tom Maniatis, D.R. Higgs, L.M. Kunkel, J.L. Mandel, and Y.W. Kan, respectively. The EJ 6.6 clone was from American Type Culture Collection (ATCC 41028). We are grateful to Dr. Chun-Ying Chang for referral of some of the patients, to Prof. Hsu-Wen How, Department of Pathology of the University, for histologic examination, and to Prof. Ding-Shinn Chen, Graduate Institute of Clinical Medicine of the University, for various forms of assistance.

Transplacental, amniotic, urinary, and fetal fluid dynamics during very-large-volume fetal intravenous infusions

Robert A. Brace, PhD, and Thomas R. Moore, MD
La Jolla, California

With rapid intravenous infusion of very large volumes of isotonic saline solutions into the fetus, the fluid could stay within the fetal body, thereby creating hydrops fetalis, be transferred into the amniotic fluid through the fetal kidneys, thereby creating polyhydramnios, or be transferred across the placenta into the maternal circulation. This study was designed to explore these possibilities. After a 1-hour control period, 10 near-term chronically catheterized ovine fetuses were infused intravenously with 4 L (>100% of fetal weight) of either isotonic saline solution or lactated Ringer's solution over 4 hours. Fetal arterial pressure was significantly elevated by 7 mm Hg throughout the infusion ($p < 0.00001$). Venous pressure underwent a transient rise (4.8 mm Hg) at 20 minutes of infusion and remained elevated (2.7 mm Hg) during the rest of the infusion ($p < 0.00001$). Fetal urine flow increased by an average of 5.7 ± 0.4 ml/min throughout the infusion ($p < 0.00001$) and accounted for 34.1% ± 2.6% of the infused volume. Estimated fetal extracellular fluid volume increased by 17.7% ± 1.8% of the infused volume. Because fetal fluid retention, urine flow, and amniotic fluid volume changes accounted for only half of the infused fluid, the remainder of the infused volume must have crossed the placenta and entered the maternal circluation. Given the above changes in vascular pressures, this requires a filtration coefficient of the placenta 50 to 100 times the previously reported values. Thus we conclude that relatively small changes in fetal vascular pressures dramatically alter the filtration capacity of the ovine placenta and transplacental volume flow. (AM J OBSTET GYNECOL 1991;164:907-16.)

Key words: Fetus, urine flow, amniotic fluid volume, fluid balance, placental transfer

In spite of the fact that fetal fluid balance has been studied for a number of years, there presently exists little practical understanding of what factors control the amount of fluid within the fetal compartment. Thus the underlying pathophysiologic characteristics of conditions such as hydrops fetalis or polyhydramnios are largely unknown. From theoretical considerations it is clear that both hydrostatic and osmotic forces are important determinants of the rate of transplacental fluid movement, as are the placental permeability characteristics.[1-3] However, it is unclear whether any or all of these are altered when hydrops fetalis or polyhydramnios is present.

In a recent study, we gradually infused 7 L of an isotonic physiologic saline solution into the circulation of chronically catheterized ovine fetuses over 3 days.[4] Surprisingly, the fetuses did not become edematous even though the infused volume was more than twice their body weight. Only 2 L of the 7 L infused remained within the amniotic and allantoic compartments at autopsy. Thus the fetal sheep appears efficient at transferring excess water and solute to the maternal compartment over a period of days.

Presently it is not known whether the fetus is capable of significant transfer of isotonic saline solutions to the maternal compartment over shorter time intervals. The present study was designed to test this possibility. In addition, we explored whether osmotic or hydrostatic forces mediate fetal-to-maternal transfer by comparing responses to fluids of different composition, that is, 0.9% saline solution and lactated Ringer's solution.

Methods

Chronically catheterized fetal sheep were surgically prepared and maintained as described in detail elsewhere.[5-7] During aseptic surgery with animals under gas inhalation anesthesia, catheters were implanted in the fetal descending aorta, inferior vena cava, urinary bladder, and amniotic fluid, as well as in the maternal descending aorta. Experiments were conducted 5 or more days after surgery while the ewe was housed in a metabolic cart. These experiments were approved by our institution's animal subjects committee.

During the experiments, fetal arterial pressure, venous pressure, heart rate, amniotic fluid pressure, and urine flow rate were continuously recorded as previ-

ously described.[8, 9] Fetal vascular pressures were referenced to amniotic fluid pressure.[8]

Each experiment began with a 60-minute control period. At the end of the control period, 4000 ml of either warmed (40° C), lactated Ringer's solution (Baxter Corp., Deerfield, Ill.; measured osmolality, Na^+, K^+, and Cl^- concentrations: 251 mOsm/kg, 125 mEq/L, 4.0 mEq/L, and 110 mEq/L, respectively; $n = 5$) or 0.9% saline solution (Baxter Corp.; measured osmolality, Na^+, K^+, and Cl^- concentrations: 289 mOsm/kg, 152 mEq/L, 0.2 mEq/L, and 149 mEq/L, respectively; $n = 5$) were infused into the fetal circulation over 4 hours (that is, at a rate of 16.7 ml/min). Termination of the infusion was followed by a 1-hour recovery period.

Samples of fetal arterial blood, urine, and amniotic fluid as well as maternal arterial blood were taken at 30 to 60 minute intervals for measurement of osmolality (Advanced Instruments, Inc., Needham Heights, Mass.; freezing point depression) and Na^+, K^+, and Cl^- concentrations (model 5 + 5 electrolyte analyzer, Nova, Waltham, Mass.). From eight animals, fetal blood was also collected and assayed for plasma arginine vasopressin and atrial natriuretic factor concentrations as previously described.[10] Fetal blood was replaced after each sample with an equal volume of heparinized maternal blood, which was collected before the experiment. Fetal and maternal blood gases and pH were measured with an automated blood gas analyzer (model 1306, Instrumentation Laboratory, Lexington, Mass.) and were corrected to fetal (39.5° C) and maternal (39° C) body temperatures.

At 60-minute intervals ultrasonography (3.5 MHz linear-array scanner, Sonoline, Japan) was used to determine fetal thoracic, abdominal, and cardiac diameters in two dimensions. For each measurement a mean was taken from triplicate determinations. Cross-sectional areas were calculated from the product of the two diameters. Ultrasonography also was used to determine the presence or absence of free fluid within the fetal abdominal, thoracic, and pericardial cavities. In preliminary experiments with a catheter inserted into these spaces, if 5 to 10 ml or more of saline solution was injected into either the abdominal or thoracic cavity, it was detectable with our ultrasonographic method.[11] Amniotic fluid volume was estimated at hourly intervals as the mean of a triplicate determination of the four-quadrant sum for the amniotic fluid index.[12] These estimates of the amount of free fluid in the fetus and amniotic fluid volume should be interpreted continuously because our preliminary studies[11, 12] were conducted in fetuses that had been euthanized.

Fetal arterial blood volume as a percent of control was calculated from fetal hematocrits as previously described.[13] The method is valid because the ovine fetus does not have a pool of releasable red blood cells such as occurs in the spleen of the adult.[13] Fetal extracellular fluid volume changes as a fraction of control values were calculated from plasma protein concentrations by dividing the mean plasma protein concentration during the control period by that at the time of each sample. This calculation is based on the assumption that the plasma proteins rapidly distribute between the plasma and interstitial spaces and is supported by our previous observation that the capillary permeability to proteins in fetal sheep averages 15 times adult values.[14] The absolute changes in extracellular fluid volume were then calculated as the product of the above fraction, fetal weight, and an assumed initial extracellular fluid volume of 320 ml/kg.[15, 16] Although we do not know the accuracy of this approximation, it most likely overestimates the actual changes in extracellular fluid volume because the infusions would directly dilute plasma proteins and wash them into the interstitial spaces.

After the experiments the animals were euthanized with 300 mg/kg pentobarbital. The fetuses were removed, towel dried, weighed, and autopsied. No correction was made in fetal weight for fluid retained within the fetus. The net effect of the latter on the extracellular fluid volumes calculated as described above would be to overestimate the initial extracellular fluid volume at the start of the experiment and thus to overestimate the extracellular fluid volume change throughout the infusion.

Not all values were measured in every animal. Fetal urine flow rates were measured in only nine of the 10 animals because a urinary bladder catheter was not placed in one animal. Ultrasonographic measurements were made in only eight of 10 animals. Within these eight animals fetal cardiac dimensions could not be determined at all time points because of shadowing caused by positioning of the fetal bones. Maternal values were monitored in only six of the 10 animals because we were not anticipating the extensive and rapid transplacental volume shift in the first few animals.

Statistical analysis. The continuously measured fetal variables are presented as 10-minuted averages. All data are presented as the mean ± SE and were analyzed for statistically significant changes with time by a two-factor analysis of variance for repeated measures, with time and animal being the two factors. To statistically compare responses during saline solution versus Ringer's infusion, a three-factor analysis of variance was used, with time, treatment, and animal being the three factors. A significant difference in the responses of the two groups occurred when a statistically significant interaction between time and treatment was present. A value of $p < 0.05$ was taken as statistically significant, and the described changes were significant at

Table I. Fetal and maternal arterial pH, blood gases, hematocrit, and plasma protein concentration during 60-minute control period

Variable	*Fetal*	*Maternal*
Arterial pH	7.345 ± 0.007	7.457 ± 0.007
Carbon dioxide tension (mm Hg)	50.9 ± 1	36.9 ± 0.9
Oxygen tension (mm Hg)	22.1 ± 0.6	103 ± 3
Hematocrit (%)	33.3 ± 0.9	29.8 ± 1.6
Plasma protein (gm/dl)	3.6 ± 0.1	6.7 ± 0.2

Data expressed as mean ± SE. $n = 10$ for fetal values, and $n = 6$ for maternal values.

Table II. Fetal and maternal osmolalities and electrolytes during 60-minute control period

Variable	*Fetal plasma*	*Maternal plasma*	*Fetal urine*	*Amniotic fluid*
Osmolality (mOsm/kg)	296.9 ± 1.0	300.2 ± 0.9	129.7 ± 7.6	241.3 ± 9.4
Sodium (mEq/L)	142.0 ± 0.6	146.7 ± 0.7	43.7 ± 5.7	101.8 ± 6.1
Potassium (mEq/L)	4.3 ± 0.1	4.1 ± 0.2	5.1 ± 1.6	6.8 ± 1.2
Chloride (mEq/L)	110.9 ± 0.7	115.1 ± 0.5	37.8 ± 4.4	90.1 ± 5.9

Data expressed as mean ± SE. $n = 10$ for fetal plasma and amniotic fluid, $n = 9$ for fetal urine, and $n = 6$ for maternal plasma.

this level unless otherwise specified. If the analysis of variance was significant, differences among means were analyzed with Fisher's least significant difference test for multiple comparisons. If the responses to the infusion of 0.9% saline solution were not significantly different from the responses to the infusion of lactated Ringer's solution, the data were combined and only the mean responses of all animals were presented. Occasionally, symbols within the figures have no visible SE bars because the SE lies within the symbol.

Results

Fetal age was 134 ± 2 (SE) days' gestation (range, 127 to 141 days; term, 145 to 150 days) on the day of experimentation. During the 60-minute control period, fetal arterial pressure was 43.4 ± 1.0 mm Hg, venous pressure was 3.4 ± 0.3 mm Hg, heart rate was 154 ± 5 beats/min, urine flow was 0.67 ± 0.07 ml/min, plasma arginine vasopressin was 1.5 ± 0.1 pg/ml, and plasma atrial natriuretic factor was 166 ± 17 pg/ml. Additional fetal and maternal values during the control period are listed in Tables I and II. These are consistent with normal values from this laboratory.

In response to the infusion, fetal arterial pressure increased significantly (mean, 7.4 mm Hg; $p < 0.00001$) and was maintained throughout the 4-hour infusion (Fig.1). During the 1-hour recovery period, arterial pressure decreased significantly to 2.9 mm Hg below control values. Although there were highly significant increases in fetal venous pressure ($p < 0.00001$), the response differed from the arterial pressure response in that a transient maximum of only 4.8 mm Hg occurred at 20 minutes, followed by a maintained increase of 2.7 mm Hg throughout the remainder of the infusion period (Fig. 1). In addition venous pressure returned to, but not below, preinfusion values during the recovery period. Fetal heart rate underwent a small transient rise with a peak of 14 ± 5 beats/min above control ($p = 0.031$) at 40 minutes and returned to values not significantly different from control within an additional 30 minutes (Fig.1). Amniotic fluid pressure increased significantly during the infusion ($p = 0.00001$), averaging 2.1 mm Hg above control during the last hour of infusion. Amniotic fluid pressure remained at this level during the recovery period. When the responses are compared in the fetuses infused with saline solution and in those receiving lactated Ringer's solution, there were no significant differences in fetal arterial, venous, or amniotic fluid pressures or heart rate.

During the infusion there were significant decreases in fetal hematocrit ($p < 0.01$) and plasma protein concentration ($p < 0.00001$), as seen in Fig. 2. During the recovery period hematocrit increased to above control values whereas plasma protein concentration remained reduced. These changes in hematocrit correspond to a 3.2% ± 0.7% increase in blood volume throughout the infusion and a 5.6% ± 1.4% reduction afterward (Fig. 2). In contrast to these small changes in blood volume, extracellular fluid volume increased by 58.0% ± 3.4% during the last hour of infusion and remained elevated by 31.2% ± 3.5% ($p < 0.00001$) at the end of the recovery period (Fig. 2). These changes in extracellular fluid volume correspond to a 17.7% ± 1.8% retention of the infused fluid within the fetal extracellular compartment at the end of the infusion and an 8.5% ± 0.9% retention at the end of the recovery period. Again there were no statistically significant differences in the

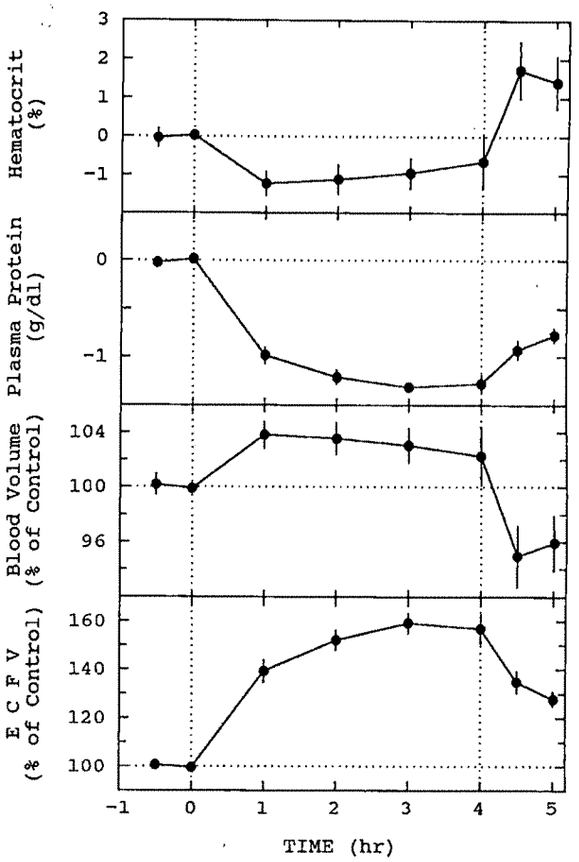

Fig. 2. Fetal hematocrit, plasma protein concentration, blood volume, and extracellular fluid volume *(ECFV)* responses to the infusion of 4 L/4 hr starting at time 0. Data are mean ± SE (n = 10) and are expressed as either a change or a percent of mean values during he control period. *Vertical dotted lines* indicate start and end of 4-hour infusion.

responses to infusion of 0.9% saline solution compared with infusion of lactated Ringer's solution.

In contrast to similar fetal pressure and volume changes, there were major differences in fetal plasma composition changes during the infusion of saline solution versus infusion of lactated Ringer's solution. As seen in Fig. 3, fetal osmolality decreased by 3.1 mOsm/kg at the end of the Ringer's infusion compared with a 7.6 mOsm/kg increase in the fetuses given saline solution (p = 0.0017, comparison of the two groups). Plasma Na^+ concentration was unchanged during Ringer's infusion and increased by 7.0 ± 0.3 mEq/L during saline solution infusion ($p < 0.00001$). Plasma Cl^- increased by 2.9 ± 1.1 mEq/L at the end of Ringer's infusion; this was significantly less ($p < 0.00001$) than the 13.9 ± 2.3 mEq/L increase during saline solution infusion (Fig. 3). Finally, although plasma K^+ concentration decreased in both groups, the decrease was much greater ($p < 0.00001$) during saline solution infusion.

The changes in maternal plasma composition were less than the fetal changes (Fig. 4). Although maternal osmolality decreased by an average of 1.8 ± 1.0 during the last 2 hours of the Ringer's infusion compared with a 1.8 ± 0.8 mOsm/kg increase during saline solution infusion, the differences were not statistically significant (p = 0.11). Maternal plasma Na^+ concentration was unchanged during Ringer's infusion and increased by 1.6 ± 0.3 mEq/L during fetal saline solution infusion; this difference was significant (p = 0.027). Maternal plasma Cl^- and K^+ were unchanged with time in either group, and there were no significant differences between the two groups in either Cl^- or K^+ responses. In addition, there were no statistically significant changes in maternal hematocrit or plasma protein concentration with time.

The changes in fetal and maternal plasma electrolytes and osmolality were accompanied by changes in the transplacental gradients in osmolality and electrolyte concentrations as seen in Fig. 5. The gradients in

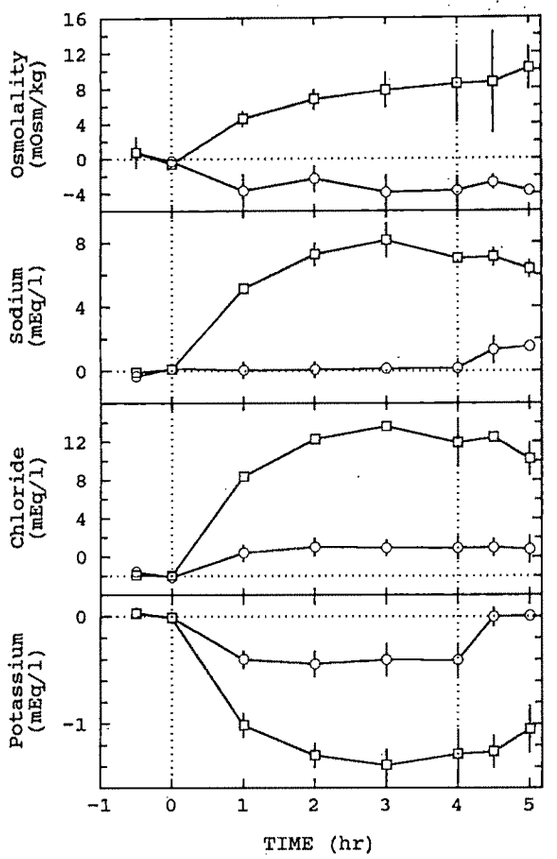

Fig. 3. Fetal plasma osmolality and electrolyte concentration changes in response to infusion of 4 L/4 hr starting at time 0. *Circles,* Ringer's infusion; *squares,* 0.9% saline solution infusion. Data expressed as mean ± SE changes from values during 1-hour preinfusion period.

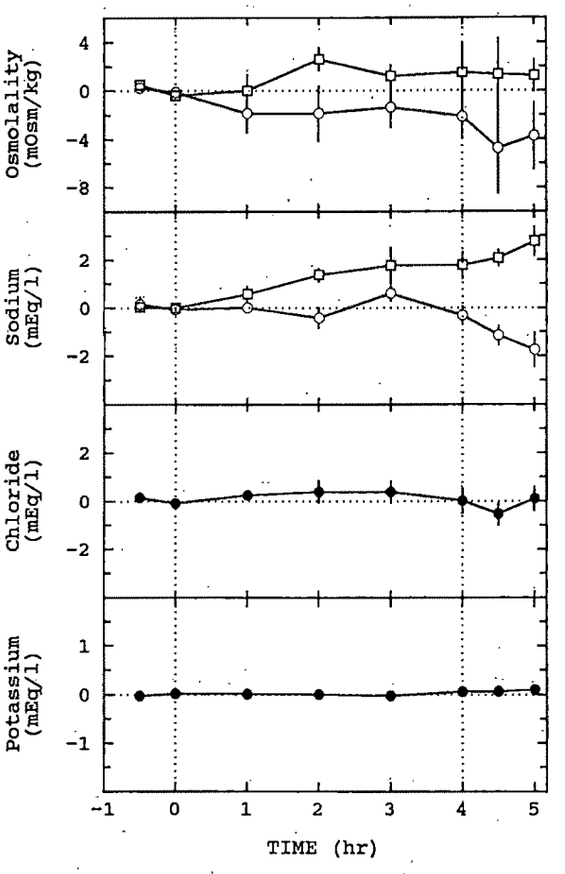

Fig. 4. Maternal plasma osmolality and electrolyte changes in response to infusion of 4 L/4 hr into fetal circulation starting at time 0. *Circles,* Ringer's infusion; *squares,* 0.9% saline solution infusion; *filled circles,* combined Ringer's plus saline solution infusion when no significant differences existed between the two groups. Data expressed as mean ± SE changes from values during 1-hour preinfusion period.

plasma osmolality, Na^+, Cl^-, and K^+ were each significantly different in animals given saline solution versus animals given lactated Ringer's solution ($p < 0.01$ for all).

Fetal urine flow rate underwent very large increases during the infusion ($p < 0.00001$), as seen in Fig. 6. Urine flow increased gradually throughout the 4-hour infusion and was 7.7 ± 0.5 ml/min above control at the end of the infusion period. On the average, urine flow increased by a mean of 5.7 ± 0.4 ml/min throughout the 4-hour infusion. This corresponds to 34.1% ± 2.6% of the infused volume. Urine flow rate decreased rapidly after termination of the infusion (Fig. 6) and was 2.3 ± 0.4 ml/min above control at the end of the 1-hour recovery period. The urine flow response was not significantly different in fetuses given saline solution versus fetuses given lactated Ringer's solution.

There were large and highly significant increases ($p < 0.00001$) in fetal urine osmolality and in Na^+ and Cl^- concentrations in response to the infusion (Fig. 7); urine K^+ concentration was unchanged. Although there were no statistically significant difference between fetuses given saline solution and fetusus given Ringer's solution, urine Cl^- tended to increase more in the fetuses given saline solution ($p = 0.108$). During the last hour of infusion the composition of fetal urine was essentially the same as that of the infusate during Ringer's infusion (mean osmolality, 255 mOsm/kg; Na^+, 121 mEq/L; K^+, 3.1 mEq/L; Cl^-, 103 mEq/L), and was slightly less concentrated as compared with the infusate during 0.9% saline infusion (mean osmolality, 269 mOsm/kg; Na^+, 132 mEq/L; K^+, 2.4 mEq/L; Cl^-, 122 mEq/L).

Although there were highly significant ($p < 0.0001$) increases in fetal plasma atrial natriuretic factor in response to the infusion (Fig. 8), the changes did not parallel those in fetal urine flow. In addition, there was a rise in the mean plasma arginine vasopressin concen-

Fig. 5. tration (Fig. 8), but this was not significant because arginine vasopressin was unchanged in half of the fetuses and rose in the other half.

There were multiple changes in amniotic fluid composition during the infusion (Fig. 9). Amniotic fluid osmolality ($p = 0.0021$), Na^+ concentration ($p = 0.0001$), and Cl^- concentration ($p = 0.0004$) increased significantly, and there were no differences in the fetuses given saline solution versus those given Ringer's solution. In contrast, the decrease in amniotic K^+ concentration was significantly greater ($p = 0.0008$) in the fetuses given saline solution (Fig. 9).

Fetal arterial oxygen and carbon dioxide tensions were unchanged in response to the infusion (Fig. 10). Fetal pH decreased significantly during both infusions ($p < 0.00001$), but the decrease was significantly greater during saline solution infusion ($p < 0.030$). Maternal blood gas tensions and pH were unchanged in both groups, and there were no significant differences between groups in the maternal values.

As determined ultrasonographically, neither fetal thoracic nor pericardial cross-sectional area changed significantly during the infusion (Fig. 11). Fetal abdominal area increased by 41.1% ± 12.7% ($p < 0.01$) and remained elevated during the recovery period (Fig. 11). No free fluid was detected within the thoracic cavity in any of the fetuses. In addition, even with the increase in abdominal area, we detected no free fluid in four of eight fetuses; minimal ascites was observed in two, and mild ascites was seen in the remaining two fetuses. In half of the fetuses we observed with ultrasonographic examination a notable increase in the volume of fluid within the rumen. The amniotic fluid index averaged 105 ± 21 mm during the control period; it increased by 191% ± 59% ($p < 0.001$) at the end of the infusion period (Fig. 11.)

Fetal weight at autopsy was 3.95 ± 0.32 kg. None of the fetuses were hydropic at autopsy. This fetal weight is slightly, but not significantly, greater than that in other fetuses studied in this laboratory at the same gestational age,[4] but not subject to rapid infusions.

Comment

In this study we intravascularly infused the ovine fetus at a rate of 16.7 ml/min for 4 hours with physiologic saline solutions so the total infused volume was 4000 ml. Because this volume was in excess of fetal weight, we anticipated that the fetuses would become severely edematous. This expectation of fetal edema was based on a series of previous studies in the fetal sheep:

1. In response to acute vascular volume loading of smaller magnitudes, the maximal increase in fetal urine flow was <1 ml/min,[9] so that only a very small fraction of the infused fluid was expected

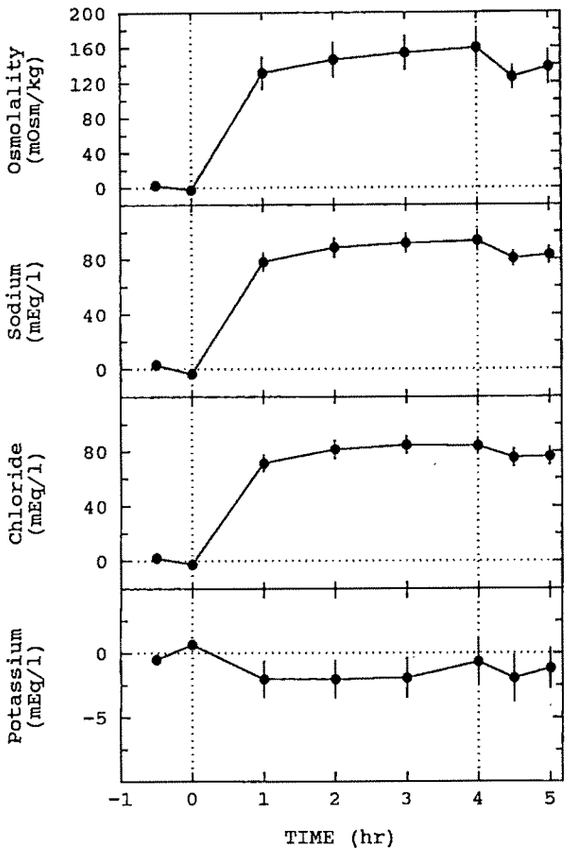

Fig. 7. Changes in fetal urine osmolality and electrolyte concentrations in response to infusion of 1 L/hr of Ringer's solution or saline solution into fetal circulation from time 0 to 4 hours. Data expressed as mean ± SE from values during 1-hour control period.

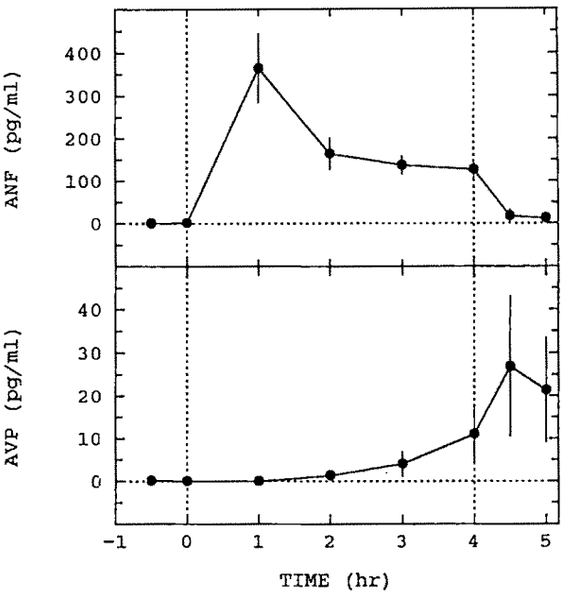

Fig. 8. Mean ± SE fetal plasma atrial natriuretic factor *(ANF)* and arginine vasopressin *(AVP)* responses to the infusion of 4 L/4 hr of fluid into the fetal circulation. Data expressed as changes from mean values during 1-hour control period.

to be excreted through the fetal kidneys. Even with long-term volume loading over a period of days, the maximal increase in fetal urine flow was 5 ml/min,[4] again suggesting only a small fraction of the fluids infused in the present study would be excreted by the kidneys.

2. The placental filtration coefficient in the chronically catheterized sheep has been reported to be 0.0067 ml/min/kg of fetal weight[17] or roughly 0.025 ml/min for fetuses with an anticipated weight of 3.5 kg. With this filtration coefficient, an increase in fetal vascular pressures of 667 mm Hg would be required to hydrostatically drive the infused 16.7 ml/min across the placenta. This is not likely in view of the normal arterial and venous pressures of 45 and 3 mm Hg, respectively, in the fetuses.
3. Although the late-gestation fetus normally secretes roughly 0.2 ml/min of fluid from its lungs, the lung secretion rate decreases with vascular volume loading.[18] Thus, by considering each of the major routes by which the infused fluid might leave the fetus, we speculated that a large fraction of the 4000 ml would remain within the fetal body at the end of the 4-hour infusion.

In contrast to this expectation, we observed that little of the infused fluid remained within the fetal body at the end of the infusion. This conclusion is based on two indirect estimates of extracellular fluid volume changes. First, we used the plasma proteins as an extracellular marker to calculate extracellular fluid volume changes. We acknowledge that this is probably a crude marker at best that, as considered in the Methods section above, probably leads to an overestimation of fetal extracellular fluid volume changes for at least two reasons. Even with the overestimations, we found only 17.7% of the infused fluid was retained within the fetal body. Second, we used ultrasonography to monitor fetal cross-sectional areas and to monitor free fluid within the thoracic and abdominal cavities. Although thoracic and pericardial areas were unchanged, abdominal area increased significantly. Because we have previously found that 5 to 10 ml of fluid injected directly into the thoracic or abdominal cavities of fetal sheep could be detected ultrasonographically,[11] our ultrasonographic monitoring suggested that only small volumes of fluid were retained within the fetal body. In addition to these two indirect estimates, fetal blood volume increased by only 3.5% during the infusion. Thus it is clear that only a small fraction of the infused fluid remained within the fetal body at the end of the infusion.

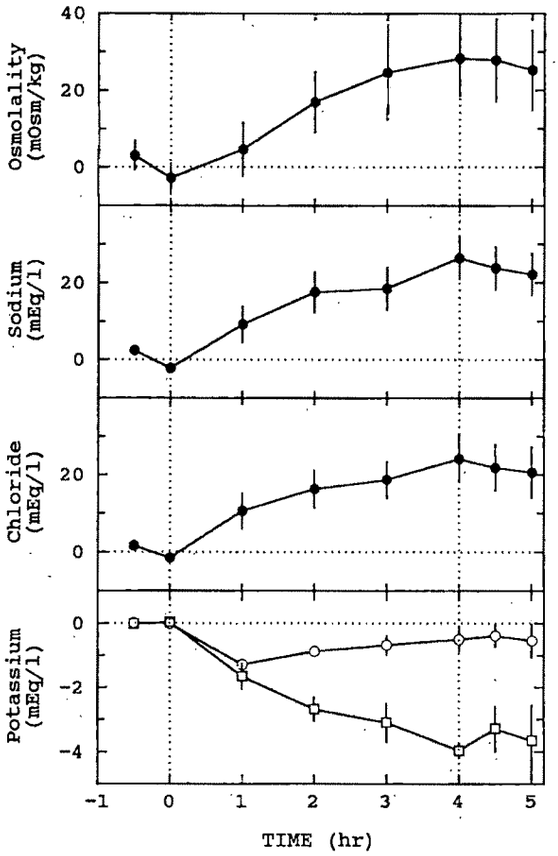

Fig. 9. Amniotic fluid osmolality and electrolyte concentration changes in response to intravascular infusion of 4 L of Ringer's solution or 0.9% saline solution into fetus from 0 to 4 hours. Data expressed as mean ± SE. *Circles,* Ringer's infusion; *squares,* 0.9% saline solution infusion; *filled circles,* combined Ringer's plus saline solution infusion when no significant differences existed between the two groups.

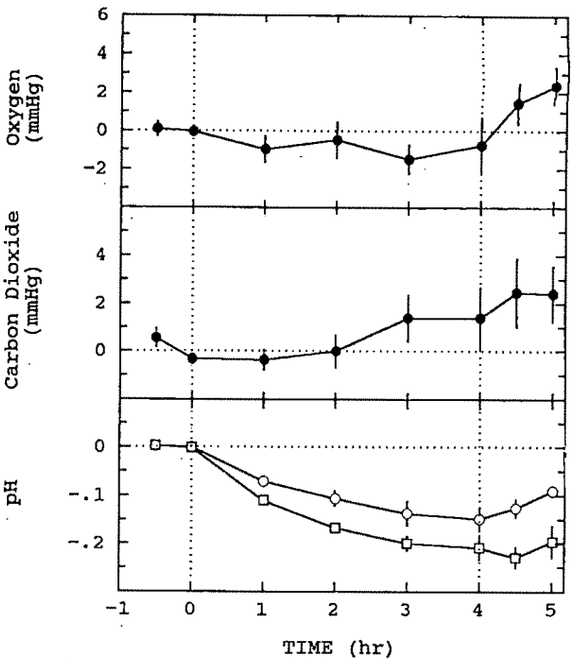

Fig. 10. Changes in fetal arterial blood gases and pH during the infusion of 4 L of Ringer's solution or saline solution into fetal circulation. Infusion was from time 0 to 4 hours. *Circles,* Ringer's infusion; *squares,* 0.9% saline solution infusion; *filled circles,* combined Ringer's plus saline solution infusion when no significant differences existed between the two groups. Data expressed as mean ± SE changes from values during 1-hour preinfusion period.

The fetal urine flow response to the infusion of 16.7 ml/min is remarkable in that the flow of 7.4 ml/min above baseline values during the last hour of infusion is by far the highest urine flow rate ever reported for the ovine fetus. In spite of this high urine flow, excretion by the fetal kidneys accounted for only 34.1% of the infused volume over the 4 hours. In addition, the change in amniotic plus allantoic fluid volume, as estimated from our previous study of the amniotic fluid index in pregnant sheep[12] agrees well with that anticipated from the measured changes in fetal urine flow. Finally, the changes in amniotic composition that occurred (Fig. 9) are those predicted if 1.4 L (i.e., 34.1% of 4 L) of urine of the measured composition was added to 1 L of amniotic fluid.

By combining the fluid excreted by the fetal kidneys with that retained within the fetal body, we could account for only 50% of the infused fluid. It is clear that the remaining 50% of the infused volume, or 2000 ml, must have crossed the placenta and entered the maternal circulation during the 4-hour infusion. Because the mean increase in arterial and venous pressures combined was only 5.2 mm Hg during the infusion, the filtration coefficient of the placenta would equal 2000 ml/240 min/5.2 mm Hg or 1.60 ml/min/mm Hg. This number is 64 times the value of 0.025 ml/min expected for fetuses weighing 3.5 kg. Thus it appears that there was a 50-fold to 100-fold increase in the filtration coefficient of the placenta during the infusion. This is remarkable because it occurred with a mean increase in venous pressure of <3 mm Hg and in arterial pressure of 7 mm Hg. These pressure increases are comparable to those that occur during acute fetal hypoxia[19, 20] and are less than those that occur during spontaneous fetal body movement. Thus, although it may be suggested that the results of this study are not physiologically relevant because of the large volumes of fluid that were administered, this argument appears invalid because the pressure changes that occurred in the fetus are well within the physiologic range.

It might also be suggested that the large rise in the placental filtration coefficient that occurred in this study was hormonally mediated. Although this is a pos-

sibility, we presently tend to discount the possibility because fetal arginine vasopressin was not consistently changed. Additionally, although fetal atrial natriuretic factor rose during the last 3 hours of the infusion, atrial natriuretic factor was only twice normal values. In view of previous studies in which exogenous atrial natriuretic factor was infused into the ovine fetus,[21] it is unlikely that the small rise in atrial natriuretic factor mediated the huge increase in placental permeability. Thus it appears that the small rise in fetal vascular pressures may have mediated the placental permeability rise.

In addition to the marked increase in the placental filtration coefficient, there appear to be major changes in the reflection coefficients of the placenta. Previously the reflection coefficients of the ovine placenta for Na^+ and Cl^- have been estimated to be approximately 0.8.[22] Considering that the changes in fetal electrolyte composition were either nonexistent or small and that urine was nearly isotonic with the infusate, it is clear that the composition of the fluid crossing the placenta must have been nearly the same as the infusate. This would require the placental reflection coefficients to be near zero for both Na^+ and Cl^-. Because these are drastically different from the value of 0.8 noted here, our observations further suggest that there were major increases in the placental permeability during the 4 L infusions. Again, a remarkable aspect of the increased permeability is that such large changes occurred in the face of only small changes in fetal vascular pressures.

There is an alternative interpretation to these data, that is, the sheep placenta normally has a high filtration coefficient and low reflection coefficients, and previous estimates of these placental permeability parameters simply may have been in error. Such errors might occur if the simplified theory used to calculate permeability failed to adequately represent the complex exchange processes within the placenta, if there are inhomogeneous permeabilities and exchanges within the placenta, or if the high osmolalities used in calculating the filtration coefficient altered the permeability characteristics of the placenta. This possibility is supported by two observations: (1) Very large volumes of fluid with Na^+ and Cl^- content many times that in the fetal body can be drained as either amniotic fluid or fetal urine over a period of many days without any indication of electrolyte or osmolality changes within the fetus[5, 22, 23]; (2) 5 L of fluid and electrolytes was transferred from the fetal to the maternal compartment during a 3-day intravascular infusion into the fetus without changes in fetal or maternal plasma composition.[4] Although the latter two observations appear to contradict the concept that the sheep placenta is a low-permeability organ, it is possible that the permeability was increased under the conditions of the volume loading and drainage experiments but the causes of these changes would be unknown. This possibility is supported by the study of Thornburg et al.,[22] in which it was suggested that arginine vasopressin may affect ovine placental permeability. It is noteworthy that, if fetal vascular pressures were to change, the changes most likely would be in the opposite direction during the drainage as compared with volume-loading experiments, so that the role of hydrostatic pressure changes under the two conditions to any adaptive changes in placental permeability would likely be in opposite directions.

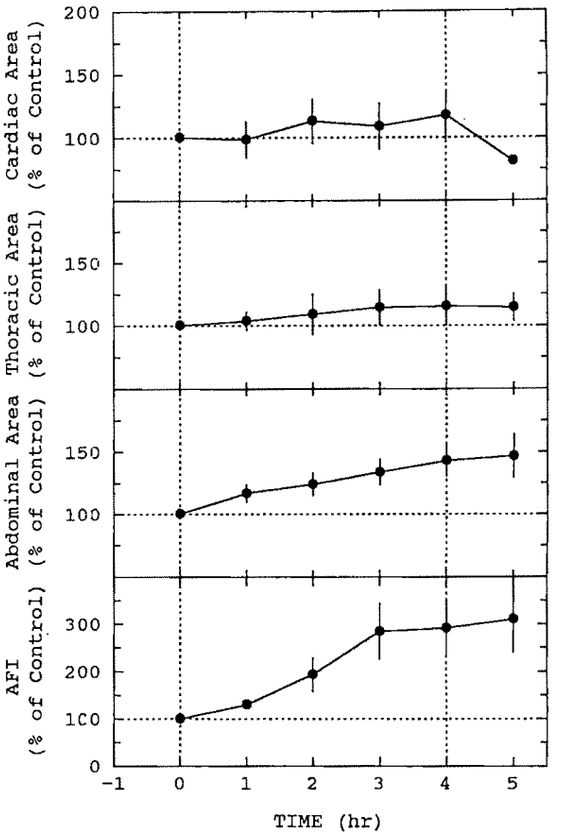

Fig. 11. Responses of fetal cardiac, thoracic, and abdominal areas and amniotic fluid index *(AFI)* to intravascular infusion of 4 L/4 hr of fluid into fetal circulation. Data expressed as mean ± SE percent of values during 1-hour preinfusion period.

In this study amniotic fluid pressure increased by 2 mm Hg at the end of the infusion period. In a recent study[24] we found that the compliance of the uterine compartment in pregnant sheep during late gestation was 1 mm Hg/L. Thus, from the increase in amniotic fluid pressure, an increase in uterine volume of 2 L would be expected in this study. This agrees with the 2 L of fluid that was estimated to be retained within the fetal body plus that excreted by the fetal kidneys

into the amniotic fluid. The latter further supports our conclusion that 2 L of fluid was transferred to the maternal compartment during this experiment. In addition, the observed changes in maternal plasma Na^+ and osmolality (Fig. 5) further support the fetal-to-maternal transfer of fluid.

Although there were several statistically significant differences in fetal plasma osmolality and electrolyte changes during the Ringer's infusion versus 0.9% saline solution infusion, there were no differences in fetal blood volume, extracellular fluid volume, or urine flow rate changes. In addition, there were no differences in the fetal vascular pressure changes between the two groups. This suggests that the large increases in placental permeability that occurred during the infusions were independent of the compositional changes in the fetus. Thus the hydrostatic pressure changes may be the primary mediators of the increased placental permeabilities.

In summary, our study shows that if huge amounts of isotonic electrolyte solutions are rapidly infused into the ovine fetus, only a small amount of fluid is retained within the fetal body and one third of the fluid is excreted through the fetal kidneys. The remainder, or roughly half, of the infused fluid appears to cross the placenta into the maternal circulation. The latter appears to be driven by surprisingly small increases in fetal vascular pressures, which produce very large increases in the placental filtration coefficient and major reductions in the placental reflection coefficients.

We sincerely appreciate the technical assistance of Sandra Miscovich, Michael Ternavan, Eddie Kwan, and Wendy Ewing.

Enhancement of germ tube formation in *Candida albicans* by β-endorphin

Steven S. Witkin, PhD, and Aliza Kalo-Klein, PhD
New York, New York

Candida albicans is a dimorphic yeast that causes vaginal infections after its transition from a budding yeast to a germinating hyphal form. We report here that physiologic concentrations of β-endorphin, a neuropeptide with immunomodulating activity produced during stress or physical exercise, stimulates germ tube formation in *C. albicans*. The percent of germination was proportional to the endorphin concentration, over the 5×10^{-12} to 5×10^{-10} mol/L range tested. β-Endorphin modified by removal of the 4-carboxy-terminal amino acids and (D-Ala^2)-β-endorphin, a peptide with a protease-resistant amino terminal end, were equally effective in stimulating germination. In contrast, *N*-acetylated β-endorphin did not stimulate germination. Antisera to β-endorphin also completely blocked β-endorphin-stimulated germ tube formation. Two clinical isolates of *C. albicans* were also responsive to β-endorphin. Stimulation of germ tube formation by β-endorphin occurred only in sera from ovulating women. Germination in sera from women using oral contraceptives, in sera from men, or in glucose beef extract broth was not influenced by β-endorphin. Thus *C. albicans* may be able to recognize and respond to neuroendocrine signals in ovulating women. (Am J Obstet Gynecol 1991;164:917-20.)

Key words: β-Endorphin, *Candida albicans*, vaginitis, stress

Candida albicans is a dimorphic yeast that resides on vaginal mucosal surfaces in approximately 20% of women without initiating any signs or symptoms of clinical disease.[1] The proliferation of the organism is regulated principally, if not entirely, by cell-mediated immune mechanisms.[2] Therefore under conditions of depressed cell-mediated immunity *C. albicans* can increase in concentration and initiate clinical disease at mucosal sites.[1] One factor associated with the change of *C. albicans* from a commensal to a pathogenic organism is its conversion from the yeast form to a germinated hyphal form. Although the yeast form can also be associated with disease, the germinated form is better able to penetrate mucosal epithelia and induce clinical infections.[3, 4]

We have been examining the relationship between immunosuppression, germ tube formation, and vaginal mucosal infection by *C. albicans*. Women with recurrent candidal vaginitis were shown to be deficient in their in vitro cell-mediated response to *Candida* antigens.[2, 5-7] The mechanism appeared to involve prostaglandin-mediated immunosuppression. The addition of prostaglandin inhibitors to cultures of patients' peripheral blood mononuclear cells resulted in a normal proliferative response to *Candida*.[7] Furthermore, vaginal fluids of patients, but not controls, contained prostaglandin E_2 (PGE_2).[8] PGE_2 is a macrophage product that induces immunosuppression by inhibiting T-cell activation.[9] Recent studies have shown that PGE_2 also directly stimulates germ tube formation in *C. albicans*.[10] Conversely, interferon gamma, a T-cell activation product,[11] inhibits germ tube formation, even in the presence of PGE_2.[10] Thus, when cell-mediated immunity is transiently compromised through a PGE_2-mediated mechanism, *C. albicans* proliferates and is stimulated to undergo a transition from the yeast to the germ tube form. These events increase the likelihood for initiating a symptomatic vaginal infection.

In this communication, we report that *C. albicans* is also responsive to a neuropeptide, β-endorphin, that possesses immunomodulatory activity. β-Endorphin is produced by the anterior pituitary gland; its level in the circulation increases during stress and strenuous physical exercise.[12] Although the immune consequences of β-endorphin–immune system interaction need further clarification, receptors for β-endorphin have been identified on macrophages[13] and T lymphocytes.[14] It appears that the binding of β-endorphin to macrophages induces PGE_2 production that subsequently inhibits interferon gamma synthesis.[13] We demonstrate here that β-endorphin stimulates germ tube formation in *C. albicans*.

	5.0×10^{-11}	150.1

*Three isolates of *C. albicans* were incubated in human serum in the presence or absence of β-endorphin. After 120 minutes, 400 cells were counted in quadruplicate and the numbers of yeast forms and germinated forms were determined.

Material and methods

Organisms. Three isolates of *C. albicans* were used in these studies. Strain 925, our laboratory standard, was initially purchased from Presque Isle Cultures (Presque Isle, Pa.). Two clinical isolates, No. 6 and No. 10, were cultured from vaginal fluid of two women with *Candida* vaginitis. The organisms were maintained on Sabouraud's agar slants at 28° C in a 5% carbon dioxide–humidified atmosphere. Under these conditions, 100% of the cells were in the yeast form. For all experiments colonies were harvested from 24-hour cultures and suspended in phosphate-buffered saline solution; concentrations were determined with a hemacytometer. Aliquots were then centrifuged and resuspended in the desired medium.

Chemicals. β-Endorphin, *N*-acetylated β-endorphin, β-endorphin lacking the 4-carboxy terminal amino acids, and (D-Ala²)-β-endorphin were obtained from Peninsula Laboratories (Belmont, Calif.). The compounds were suspended in phosphate-buffered saline solution and diluted to the desired concentration in serum.

Sera. Blood was obtained by venipuncture from healthy men and women. After clot formation, serum was collected by centrifugation, heat inactivated at 56° C for 30 minutes, and stored in aliquots at −70° C until used. Rabbit antiserum to β-endorphin was obtained from Peninsula Laboratories; sera from unimmunized rabbits were obtained from Pel Freeze Biologicals (Rogers, Ark.).

Germ tube formation. Yeast cells were suspended at a concentration of 10^8 ml in serum, and 0.1 ml aliquots were added to an equal volume of serum containing the desired concentration of β-endorphin or β-endorphin derivative. Control samples contained no additions. After 120 minutes at 37° C, 25 μl aliquots were removed in quadruplicate, and 400 cells were scored under ×200 power for yeast and germinating forms. In all experiments replicate aliquots differed by <15%. In nine separate experiments 29.0% ± 2.0% of the strain 925 yeast forms underwent germination under these conditions, in the absence of any additions.

**C. albicans* was incubated in sera from different donors in the presence or absence of β-endorphin. After 120 minutes, the percentage of yeast forms undergoing germ tube formation were determined as described in Table I.

†Concentrations of β-endorphin.

Results

Effect of β-endorphin on germ tube formation. Physiologic concentrations of β-endorphin, 5×10^{-10} to 5×10^{-12} mol/L, were tested for their effect on germ tube formation in serum, with strain 925 of *C. albicans*. As shown in Fig. 1, *A*, germ tube formation was increasingly stimulated by β-endorphin over the range of concentrations tested. At 5×10^{-10} mol/L, germ tube formation was 160% of the level found in control samples.

Effect of *N*-terminal or carboxy-terminal modifications on ability of β-endorphin to stimulate germ tube formation. The effects of *N*-acetylated β-endorphin and carboxy-terminal–deleted β-endorphin on germ tube formation are shown in Fig. 1, *B*. Blocking the *N*-terminal of β-endorphin completely obviated its ability to affect germ tube formation. In marked contrast, deletion of the carboxy-terminal had no effect; stimulation of germ tube formation occurred to the same extent as with unmodified β-endorphin. These results suggested that the interaction of β-endorphin with *C. albicans* may be receptor mediated. β-Endorphin binds to opiate receptors by its *N*-terminal; *N*-acetylation completely blocks this binding.[15] β-Endorphin binding to macrophages occurs through a similar mechanism.[13] Conversely, β-endorphin binding to lymphocytes occurs through the carboxy-terminal end.[14]

Germ tube formation in *C. albicans* can be stimulated by free amino acids.[16] To determine whether this might be the mechanism of β-endorphin stimulation of germination, the ability of (D-Ala²)-β-endorphin to promote germ tube formation was evaluated. (D-Ala²)-β-endorphin is a modified endorphin whose *N*-terminal is resistant to proteolysis. Germ tube formation was stimulated by a mean of 128.3% with 2.5×10^{-12} mol/L and 181.5% with 5.0×10^{-11} mol/L D-Ala²-β-endorphin. This result strongly suggested that intact β-endorphin, and not its degradation products, was promoting germ tube formation.

Effect of antiserum to β-endorphin on germination. To further assess the ability of β-endorphin to promote *Candida* germination, the effect of antiserum to β-endorphin was evaluated (Fig. 2). Preincubation of β-endorphin in a 1:10 dilution of specific antiserum to β-endorphin completely obliterated its ability to influence germination; parallel incubation of β-endorphin in control rabbit sera had no effect on the stimulation of germ tube formation by β-endorphin.

β-Endorphin–induced germination in clinical isolates of *C. albicans*. To assess whether stimulation of germ tube formation of *C. albicans* by β-endorphin was a general phenomenon, two recent clinical isolates of *C. albicans* were also tested. The results (Table I) clearly demonstrated that β-endorphin was equally effective in stimulating germ tube formation in isolates from clinical material and in a laboratory strain.

Effect of serum donor on β-endorphin–induced germ tube formation. All of these experiments were performed with serum from one female donor. Germ tube formation in *C. albicans* also readily occurs in glucose beef extract broth.[10] To our surprise, β-endorphin at concentrations of 5×10^{-8} to 5×10^{-12} mol/L had no effect on germ tube formation in this medium (data not shown). It appeared therefore that a serum component might be an essential cofactor for β-endorphin–stimulated germination. To further evaluate this possibility, the ability of sera from different donors to support β-endorphin–stimulated germination was examined (Table II). In the absence of β-endorphin, all

of the sera induced germ tube formation to a similar extent. Addition of β-endorphin to sera from four premenopausal women not using oral contraceptives led to a further 32% to 76% stimulation of germination. In marked contrast, β-endorphin had no effect on germination in sera from three men and in sera from three premenopausal women who were taking oral contraceptives.

Comment

Premenopausal women constitute the group at greatest risk for *Candida* vaginitis.[1] β-Endorphin, at physiological concentrations, stimulated germ tube formation in sera from this population. Circulating β-endorphin, in common with other serum proteins, undoubtedly enters the vagina through transduction and thus can affect *Candida* residing on mucosal surfaces. β-Endorphin has, in fact, been identified in uterine fluid.[17] Thus, in ovulating women harboring *C. albicans* as a commensal organism, the induction of β-endorphin by stress or physical exertion may directly increase the probability of contracting *Candida* vaginitis.

Stimulation of *Candida* germination by β-endorphin occurred only in sera from ovulating women. A circulating component unique to these women might therefore be an essential cofactor for the use or recognition of β-endorphin by *C. albicans*. Preliminary findings indicated that the extent of β-endorphin stimulation of germ tube formation was proportional to the estradiol concentration of the serum sample (unpublished data). *C. albicans* can bind progesterone[18] and estradiol[19] by receptor-like mechanisms.

Our data suggest that β-endorphin influences germination by a hormonal effect rather than as a nutritional substrate. Whether *C. albicans* possesses a receptor for β-endorphin remains to be established. However, similar to the mechanism of β-endorphin binding to opiate receptors,[15] we demonstrated that an intact *N*-terminal was required for the stimulation of germ tubes by β-endorphin.

Coupled with our previous findings, these results suggest that there is direct communication between the nervous system, the immune system, the endocrine system, and a unicellular eukaryotic microorganism. *C. albicans* has the ability to determine, through the presence of PGE_2 or β-endorphin, or the absence of interferon gamma, when there is a localized down-regulation of cell-mediated immunity. Under these conditions, when defenses against *C. albicans* are reduced, PGE_2 and β-endorphin also directly stimulate the yeast form of the organism to undergo morphogenesis and become capable of invading the mucosal epithelia. Development by *C. albicans* of this ability to "sense" the immune, neurologic, and endocrine status of the mammalian host may contribute to its survival. Methods to inhibit PGE_2 or β-endorphin production may ultimately prove to be of value in limiting the recurrences of *Candida* infection in susceptible individuals.

The effect of volume expansion on placental blood flow in awake hypovolemic rats in late pregnancy

Peter F. Boekkooi, MD, Carla M. Verkeste, BSc, and Louis L.H. Peeters, MD, PhD
Maastricht, The Netherlands

Symptomatic hypovolemia in preeclampsia is often treated by volume expansion. However, the effect of this treatment on placental blood flow is unclear. In the present study the hypothesis was tested that slow volume expansion, imposed on volume-depleted rats, does not compromise placental blood flow. Mild hypovolemia was induced in rats in late pregnancy by 24 hours' thirsting. The resulting gradual dehydration was associated with a 7% reduction in blood volume. These rats were then subjected to blood volume expansion by a continuous infusion with a plasma substitute. Volume expansion increased blood volume by 32% and cardiac output by 73%. The extra cardiac output was distributed to kidneys, carcass, and portal bed. Placental blood flow decreased by 31%. The pattern of response was comparable to the one previously observed in normovolemic rats. However, the magnitude of the changes was larger, probably associated with a delayed or impaired diuretic response. These data suggest that volume expansion therapy in midly hypovolemic pregnant rats elicits an exaggerated hemodynamic response as compared with normovolemic rats, including placental compromise. (AM J OBSTET GYNECOL 1991;164:921-6.)

Key words: Pregnancy, rat blood volume, cardiac output, microspheres, placental blood flow, preeclampsia

The only causal treatment for preeclampsia is delivery of the fetus. However, when the gestational age is less than ≈ 30 weeks, the fetal risks associated with premature birth may be higher than those associated with preeclampsia. In recent years, symptomatic treatment by volume expansion with plasma or plasma substitutes has rapidly gained popularity. The objective of this therapy is to "correct" the contracted plasma volume compartment in this disease.[1] It has been shown that this regimen is often associated with a dramatic improvement in the patient's clinical condition, with rapid amelioration of the reduced cardiac output, marginal urine output, and elevated peripheral vascular resistance.[2-4] However, subjecting a patient to this treatment requires admission to an intensive care unit and hemodynamic monitoring with a Swan-Ganz catheter.[5] In addition, it is still unknown how the uteroplacental blood flow responds to relatively rapid volume expansion. Data have been reported that suggest a variable decrease[6] and increase in uteroplacental blood flow[7, 8] after volume expansion, but the employed techniques, isotope dilution[6, 7] and Doppler velocity measurements in a branch of the uterine artery,[8] provide only indirect information on uteroplacental blood flow.

6/1/26355

The input for volume regulation is primarily produced in venous and atrial stretch receptors.[9] These veins also have the intrinsic capacity to dilate slowly in response to a rapid increase in intraluminal pressure, the so-called stress-relaxation phenomenon.[10] However, little is known about the impact on these two important aspects of long-term factors such as chronic venous underfilling (preeclampsia), or the chronic exposure of the veins to a certain endocrine environment (pregnancy). In previous studies on volume regulation in the awake, normovolemic rat in late pregnancy, the hemodynamic effect of gradual volume load was found to consist of a marked dilatation of large veins, an increase in cardiac output in excess of nutritional requirements, and a consistent fall in uteroplacental blood flow.[11] The reduced venous filling state and increased venous tone[9, 12] in steady-state hypovolemia are likely to cause a different hemodynamic response to a given gradual volume expansion. Particularly, the effect on the uteroplacental blood flow is uncertain. If the response is similar to that in normovolemia, uteroplacental blood flow can be expected to fall in response to volume load. On the other hand, "correction" of the hypovolemia may also reduce sympathetic tone, and thus permit a rise in uteroplacental blood flow.

The present study was designed to test the hypothesis that volume expansion in stable, hypovolemic rats in late pregnancy not only increases cardiac output and diuresis, but also uteroplacental blood flow as a result of neutralization of the hypovolemic stress. To this end, rats in late pregnancy that were mildly hypovolemic

because of 24 hours' thirsting, were subjected to slow, subacute volume expansion by a steady-state infusion with a plasma substitute (Haemaccel, Hoechst, Amsterdam). Cardiac output and regional blood flows were measured with microspheres before and after 2 hours' volume load. To determine the contribution of pregnancy to the volume response, the same experiments were also performed in a nonpregnant control group. The rat was considered a suitable model for this study because of its hemotrichorial placenta and its gestational rise in blood volume.[13] In addition, the hormonal changes in rat pregnancy resemble those in human pregnancy.

Material and methods

The study was performed in 20-days pregnant hypovolemic Wistar rats ($n = 7$) and nonpregnant hypovolemic Wistar rats ($n = 6$) obtained from a local breeder (HSD, Zeist, The Netherlands). A separate group of 20-days pregnant rats served as controls for the pregnant rats ($n = 7$). Three days before the experiment, the rats were anesthetized with ether, and polyethylene catheters (PE-10, outer dimension/inner dimension = 0.61/0.28, heat-sealed to a piece of PE-50 tubing, outer dimension/inner dimension = 0.92/0.58) were inserted into the right carotid artery, a femoral artery, and a femoral vein, and advanced into the left ventricle of the heart, the abdominal aorta, and the inferior vena cava, respectively. The catheters were tunneled subcutaneously and exteriorized between the shoulder blades. One day before the experiment, the rats were habituated to the large metabolism cages in which the experiments were to be performed.

After a recovery period of 2 days (in pregnant rats, day 19 of pregnancy), the rats in the pregnant and nonpregnant groups were deprived of water. After 24 hours' thirsting, the catheters were connected and elongated. Mean arterial pressure (MAP) and heart rate were monitored continuously for 30 minutes before the bolus injection until after the second injection of microspheres. Urine output was measured every 30 minutes. When heart rate and MAP had been stable for at least 30 minutes, cardiac output and its distribution were determined with 15 μm microspheres with the use of the reference sampling technique.[14] To this end, approximately 1.2×10^5 radioactive microspheres (NEN, Dreieich, Federal Republic of Germany) suspended in 0.2 ml saline solution with a drop of polysorbate 80 (0.05%) added to prevent aggregation, were injected into the left ventricle of the heart over a period of 15 seconds while a reference sample was withdrawn from the abdominal aorta at a rate of 0.5 ml/min. Reference sampling encompassed the period between 10 seconds before the microspheres injection and 30 seconds after its completion. The blood withdrawn was replaced with fresh heparinized blood from a donor Wistar rat. After the baseline microspheres experiment, an intravenous bolus injection of plasma substitute (2 ml) was administered, followed by a 2-hour infusion at a rate of 6 ml/hour. Haemaccel plasma substitute is an isotonic colloid solution composed of a polymer of urea and polypeptides. It is readily excreted in the urine with little metabolic breakdown. The agent is isotonic and does not leak appreciably into the interstitial space after intravascular administration.[15] Haemaccel plasma substitute is known to be well tolerated in the rat, with no measurable effect on MAP, heart rate, and respiratory rate, even when infused in large amounts.[16]

After 2 hours of continuous infusion, the microspheres experiment was repeated with a different radioactive label. In the control group only one blood flow measurement was performed after a stabilization period of at least 30 minutes. During the experiment changes in blood volume were calculated from the ob-

served changes in hematocrit (hematocrit, volume percentage, microcapillary technique). In a preceding validation study in five nonpregnant rats, plasma volume and red cell volume were determined before and after volume expansion on the basis of the indicator (albumin, labeled with iodine 125, and erythrocytes, labeled with chromium 51, respectively) dilution technique.[17] Blood volume changes calculated from the isotopes data and those based on the simultaneously measured change in hematocrit, differed by less than 5%. This result together with the minimum need for blood sampling and no requirement for the use of isotopes, led us to adopt the hematocrit method for the estimation of blood volume changes in the present study.

After the second microspheres experiment, the animals were killed with an overdose of pentobarbital. All organs were dissected and weighed. The radioactivity in each tissue aliquot and reference sample was determined with a sodium crystal scintillation counter (Packard, Groningen). Cardiac output was calculated as follows:

$$\text{Cardiac output (milliliters/minute)} = \frac{\text{Counts per minute in total body} \times \text{Reference sampling rate}}{\text{Counts per minute in reference sample}}$$

Regional blood flows were then calculated as cardiac output × fractional entrapment of microspheres as described in detail elsewhere.[18] Mixing of the microspheres after injection was considered adequate in all animals on the basis of a less than 5% difference in fractional entrapment of microspheres in the two kidneys.[19] The number of microspheres recovered in the reference samples ranged from 400 to 700.

Data are presented as means ± SD. Paired data obtained after volume load and in baseline were evaluated with the Wilcoxon signed rank test. Differences between pregnant and nonpregnant rats and between pregnant and control rats were tested by the Mann-Whitney U test. A probability of <5% (two-sided) was considered significant.

Results

One day of water deprivation decreased blood volume by 7% in both groups. Table I lists the baseline values for cardiac output, MAP, systemic vascular resistance, stroke volume, and body weight after 1 day of hypovolemia and those in the control group. Pregnant rats were heavier than their age-matched nonpregnant countermates. Neither by paired analysis nor by comparison of data of the pregnant rats with the control group did any of the hemodynamic variables change in response to the water deprivation. The results of this analysis were comparable to pregnant and nonpregnant rats.

Volume expansion increased blood volume by 32% and 35% in the pregnant group and the nonpregnant group, respectively (Table II). In the pregnant and nonpregnant groups, volume load increased cardiac output by 73% and 46%, and decreased systemic vascular resistance by 39% and 23%, respectively. The change in these two variables was smaller in the nonpregnant group than in the pregnant group. The rise in cardiac output was mainly a result of a rise in stroke volume. Neither MAP nor heart rate changed appreciably in the pregnant and nonpregnant groups.

The lung fraction and organ flows before and after volume expansion and those in the control group are listed in Table III. The volume load induced a rise in renal flow by 127% and 94% in the pregnant group and nonpregnant group, respectively. Portal flow increased by 60% in both groups, whereas carcass flow increased only in the pregnant group. Blood flows to brain, skin, and myometrium did not change consistently in either group. Fig. 1 summarizes the results and shows the distribution of the extra cardiac output

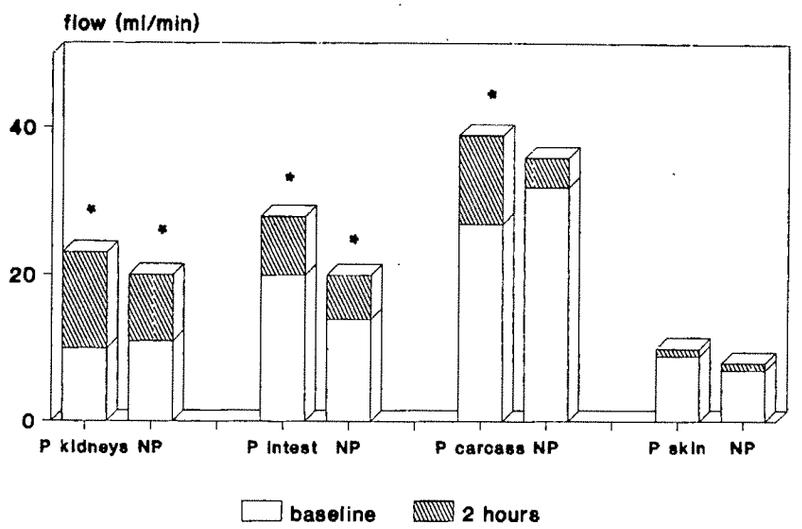

Fig. 1. Distribution of extra cardiac output after 2 hours' hypovolemia. In each pair of bars, *left bar* represents pregnant *(P)* group, and *right bar* represents nonpregnant *(NP)* group. *Asterisk* indicates significant change from baseline.

Table IV. Percentage change in hemodynamic variables in response to volume load in normovolemic and hypovolemic pregnant rats

	Pregnant state		*Nonpregnant state*

*Percentage change in hypovolemia different from that in normovolemia (Mann-Whitney U test).

in both groups. The consistent fall in fung fraction (≈ 2%) after the volume load only in the pregnant group, may at least in part be caused by secondary dislodgment of microspheres from the placental microcirculation. This phenomenon causes discrete but inconsistent underestimation of the baseline uteroplacental blood flow. Therefore uteroplacental blood flow after 2 hours infusion in the pregnant group was compared with uteroplacental blood flow in the control group. Lung fraction, litter size, fetal weight, and placental weight were comparable in the pregnant and the control groups. Uteroplacental blood flow markedly decreased in the pregnant group as compared with the value observed in the control group (180 ± 26 and 80 ± 22 ml/min per kilogram fetus, respectively, $p < 0.001$).

Finally, the magnitude of the changes induced by the volume load in the present study was compared with that previously observed in normovolemic pregnant ($n = 7$) and nonpregnant rats ($n = 6$) subjected to the same gradual volume load (Table IV). The hypovolemic pregnant rats showed a stronger hemodynamic response than that of their normovolemic countermates. This difference was not observed in the nonpregnant rats.

Comment

Maternal hypovolemia induced by 1-day water deprivation leads to gradual dehydration that includes both depletion of the extravascular space and a 7% reduction in blood volume in both pregnant and nonpregnant rats. The impact of this reduction on he-

modynamics is likely to be larger in the pregnant group inasmuch as the physiologic blood volume expansion is reversed to blood volume reduction. The constricted inferior vena cava, which was shown on x-ray film in our laboratory, complies with a decreased venous capacity after 24 hours' thirsting. It probably indicates compensatory mobilization of unstressed blood volume from the venous capacitance vessels to maintain venous return.[20] The lack of a change in cardiac output and organ flows in hypovolemia illustrates the efficacy of this compensation.

Table IV illustrates that gradual volume expansion in the mildly hypovolemic pregnant rat triggers a similar pattern of changes in cardiac output, MAP, systemic vascular resistance, heart rate, and organ flows in the normovolemic state. However, there were a number of distinct quantitative differences. First, gradual volume expansion led to a larger fluid retention in the hypovolemic rat than that in the normovolemic pregnant rat. Second, only in pregnant rat the induced cardiac output response in the hypovolemic state was significantly larger than that in the normovolemic state. This indicates that the volume load in the hypovolemic pregnant rat triggers a larger rise in stressed volume than that in the normovolemic rat. The slow onset of diuresis (after ≈ 60 instead of 20 minutes) indicates a delayed diuretic response, giving rise to a larger volume retention. This is reflected in a larger blood volume expansion in the hypovolemic (32%) than in normovolemic state (19%). Expansion of unstressed volume is likely to be limited by the elasticity of the veins, irrespective of their initial filling state.[9, 10, 21] It follows that a larger blood volume expansion can be expected to affect primarily the stressed volume compartment. In the pregnant rats, 24 hours' thirsting induced a stronger antidiuretic response than that in the nonpregnant rats (Table I). This may explain the longer delay in the onset of diuresis and larger volume expansion in response to volume expansion in the pregnant rats.

Uteroplacental blood flow also decreased consistently in the hypovolemic pregnant animal, similar to what was previously seen in the normovolemic rat. The mechanism responsible for this response is obscure. By microscopic inspection of the placentas of three pregnant rats that had been subjected to this particular volume load and the placentas of three control pregnant rats, it was shown that volume loading caused consistent selective placental congestion without concomitant distension of the venous plexus. One can speculate that gradual volume expansion and associated central venous dilatation may be paralleled by an increase in the venous resistance to flow, a phenomenon also described for preeclamptic pregnancy.[12] The rat placenta lacks venules and is equipped with rectangularly branching microchannels that cannot be opened or closed selectively. The perfusion of such a peculiar microvasculature is likely to be extra vulnerable to a rise in venous resistance. Besides, a further reduction in the already low shear forces can be expected to undermine local blood rheology, causing red blood cell sludging and enhanced formation of red blood cell aggregates.[22]

These results can be used to speculate about the hemodynamic effects of volume expansion therapy in the preeclamptic patient. In doing so, one should keep in mind that the present model differs in important aspects from the preeclamptic hemodynamic condition. The hypovolemic state in these rats is paralleled by a volume-depleted interstitium, normal blood pressure, normally grown fetuses and placentas, and normal volume regulation. The microcirculation is not impaired by enhanced capillary leakage. On the other hand, preeclampsia often couples increased venous tone and reduced venous capacitance[12] with impaired renal function. This combination increases the risk for overcorrection, defined as volume expansion in excess of maximal venous capacity. This overcorrection seems to be particularly unfavorable for uteroplacental blood flow. It follows that magnitude of diuretic response and increase in cardiac output provide incomplete information about whether volume expansion has led to correction or overcorrection of the hypovolemic state. Whether this overcorrection can be prevented by reduction of the infusion rate needs further study.

Pharmacokinetics of pentamidine in Sprague-Dawley rats in late pregnancy

Bertis B. Little, MA, PhD, Timothy H. Harstad, MD, Roger E. Bawdon, PhD, Sohrab Sobhi, BS, Daniel A. Roe, BS, Kraig A. Knoll, BS, and Fred E. Ghali, BS

Dallas, Texas

To our knowledge, placental transfer of pentamidine has not been previously studied in vivo. In the present study, the pharmacokinetics of pentamidine were analyzed in late gestation (18 days) among Sprague-Dawley rats. Pentamidine's kinetics were assessed in the following maternal compartments over a 12-hour period in 16 timed-pregnant rats: serum, liver, and kidney. Placentas were also analyzed for pentamidine concentration as were fetal brain, liver, and kidney tissues. Significant placental transfer of the drug was found, with pentamidine reaching all fetal compartments studied. Notably, by the twelfth hour fetal brain tissue achieved pentamidine concentrations that were not significantly different from those of maternal serum at the second hour of the experiment. This is an interesting observation because adult mouse and rat brains were found to be unexposed to the drug. (AM J OBSTET GYNECOL 1991;164:927-30.)

Key words: Pentamidine, pharmacokinetics, pregnancy, Sprague-Dawley rats

Pentamidine isethionate is used to treat *Pneumocystis carinii* infections in both pregnant and nonpregnant patients. Placental transfer of the drug was investigated in vitro with the perfused human placenta model. In that study,[1] therapeutic concentration of the drug was found in the placental tissue, although little drug was found in the fetal perfusate. Whether this in vitro model adequately reflects kinetics of pentamidine in vivo is unclear.

The purpose of the present study was to analyze the pharmacokinetics of pentamidine in the maternal compartment, placenta, and fetal compartment in an in vivo animal model.

Material and methods

This study protocol was reviewed and approved by the Institutional Review Board for Animal Research at the University of Texas Southwestern. The rat was chosen as the animal model because this animal showed similarity in placental transfer of another antibiotic, azidothymidine, to human beings,[2] the size is convenient for handling and dissection, and the rats have a known heritage for many generations and are genetically homogeneous. Sixteen timed-pregnant Sprague-Dawley rats were obtained from a commercial vendor (Sasco Inc., Houston) on day 9 to 10 of pregnancy, and maintained on water and Purina Rat Chow as desired until day 18 of pregnancy. On day 18 of pregnancy, rats were injected with 40 mg/kg of pentamidine in the tail vein. Four rats each were assigned to four treatment groups and were killed by decapitation at 2, 6, 8, or 12 hours after the tail vein injection with the drug. After the rats were killed, maternal samples (serum, liver, kidney), placenta, and fetal tissues (brain, liver, kidney) were collected. Fetal samples from the same mother were combined to obtain enough tissue for analysis of drug concentration. Hence, fetal measurements represent litter values and not those of individual fetuses. It was not possible to collect fetal serum samples because of the small size of rat fetuses, which is a limitation of the animal model.

The tissue was rinsed in 0.1 mol/L phosphate buffer, blotted, and approximately 0.5 gm of tissue was weighed and 2 volumes of 0.1 mol/L phosphate buffer with a pH of 6.1 was added. The samples were then homogenized with a Tissuemizer (Tekmar Co., Cincinnati), centrifuged, and injected directly into the high-performance liquid chromatography with no extraction. The methods of procedure for high-performance liquid chromatography determination of pentamidine used were as described previously without modification.[1] Standards were prepared with standard assay pentamidine isethionate provided by Lyphomed Corporation, Chicago. A standard curve was prepared in 0.1 mol/L phosphate buffer with a pH of 6.1 and these data were calculated with linear least-squares regression analysis ($R^2 = 0.98$).

Newman-Keuls multiple comparison test for analyzing the significance of differences between several means was used to analyze the pharmacokinetics data.

Testing was performed with UTSTAT computer software on the VAX 8800 computer at the University of Texas Southwestern Medical Center. Unpaired analysis was used.

Results

Means and SDs of the concentrations of pentamidine in various maternal and fetal tissues are given in Table I. Newman-Keuls multiple comparison test of differences between tissues within a specific time period are given in Table II. Two hours after injection, maternal serum concentrations of pentamidine were significantly higher than those in the placenta or any fetal tissue Table II). During the same time period, maternal kidney concentration of the drug was significantly higher than that of the placenta, but was not different from that of the fetal kidney. Maternal serum concentration of pentamidine was significantly higher than that of the maternal kidney. Maternal liver concentration of the drug was not different from that of the maternal serum, but was significantly higher than that of the fetal liver or the placenta. Six hours after administration of pentamidine, no tissue concentrations, fetal or maternal, were statistically different from maternal serum concentrations of the drug. Eight hours after intravenous injection of pentamidine, fetal brain, maternal kidney, and liver maintained pentamidine levels not significantly different from that of maternal serum. Fetal kidney, liver, and the placental concentrations of pentamidine were significantly lower than that of maternal serum. The concentration of pentamidine in maternal kidney was not significantly different from that of maternal serum, but this may be attributed to the large SD of kidney in this time period (Table I).

Fetal brain concentrations of the drug were increasing whereas in other tissues concentrations were decreasing (Table II), although the levels oscillated, probably reflecting the fact that pentamidine is biphasic. By 6 hours after injection, fetal brain achieved pentamidine levels not significantly different from those of maternal serum, and maintained high levels until the conclusion of the experiment. Fetal kidney concentrations of pentamidine suggest the fetus may be excreting large amounts of the drug because levels in the organ slightly exceeded those in the maternal serum and maternal kidney at 6 to 8 hours after injection, consistent with a biphasic pharmacodynamic effect. Fetal liver pentamidine concentrations paralleled those of the placenta, whereas drug concentrations in maternal liver were similar to those in maternal serum. It is of interest that placental pentamidine concentrations were less than those of all fetal or maternal tissue levels. Consistent with reports of the drug's half-life, concentrations of pentamidine in maternal serum decreased by about one half in the first 6 hours. Concentrations in maternal serum increased in the period 8 to 12 hours, perhaps because of fetal-to-maternal transfer of the drug, as indicated by the rise in concentrations of pentamidine in fetal kidney at 6 to 8 hours and in the placenta from 8 to 12 hours. However, the biphasic nature of pentamidine may also explain such pharmacodynamic behavior of the drug. Consequently at 12 hours after

injection, all fetal tissues and the placenta were significantly lower than maternal serum.

Maternal brain concentrations of pentamidine were measured and we concluded there was no significant penetration of the blood-brain barrier. The minimum detectable level of the drug in tissue was 0.5 μg/ml. The concentration of pentamidine in maternal brain was 1.1 ± 1.3 (mean ± SEM) μg/ml, which is 3% of the maternal serum level. Because these levels are very close to the minimum sensitivity of the high-performance liquid chromatography method, it is possible that maternal brain tissue levels of pentamidine were interfering substances (i.e., blood contamination of the brain tissue samples). We conclude that maternal brain achieved drug concentrations of pentamidine not significantly different from zero.

Comment

Pentamidine readily crossed the rat placenta and reached concentrations as high as maternal serum levels in several key fetal tissues (i.e., brain and kidney), but this may be a function of the relatively large doses used in the study (i.e., 10 times the therapeutic human intravenous dose). It is possible this high-dose regimen was able to override the protective effect of the placenta that was hypothesized in an earlier in vitro study.[1] Whereas the placenta allowed pentamidine to cross, concentrations of the drug in this tissue were invariably lower than those of other organs, maternal or fetal. Generally, drug concentrations decreased over time, with one exception, the fetal brain, which experienced a biphasic increase over time. This indicates that pentamidine readily penetrates the fetal blood-brain barrier, which is sharply different from the adult mouse brain in which no pentamidine was found over time,[5] and our results that suggested no significant penetration of the adult rat blood-brain barrier. The implications of this finding for embryo-fetal development are not known.

The high concentrations of pentamidine in the fetus may be of clinical interest. In a previous study that used pregnant animals given pentamidine over an extended period of time, investigators found a significantly increased frequency of embryonic resorptions, but no congenital anomalies.[4] It is possible that these embryonic deaths were a result of early damage of vital systems by persistent levels of pentamidine. In the human being, pentamidine is now given in an aerosolized form by inhalation, resullting in much lower serum concentrations than when the drug is administered by other routes. Pharmacokinetics of the drug at these lower doses have not been studied, but may follow a similar pattern.

Caution must be used when extrapolating findings of animal studies of both placental transfer and teratogenicity to conditions in human beings because the composition of the rat placenta and development of the rat conceptus are different from human placenta and conceptus. Human and rat placentas are both hemochorial, but in the rat there is a layer of cellular trophoblast interposed between the chorionic villus and maternal blood. This may cause species differences in

the drug's kinetics across the placenta. Despite species differences in placental morphology, the results of this study are similar to findings in in vitro perfused human placental lobules.[1]

Thumbtacks

To the Editors: I am writing to support the use of thumbtacks to obtain hemostasis in cases of intractable venous sacral hemorrhage as advocated by Patsner and Orr (Patsner B, Orr JW Jr. Intractable venous sacral hemorrhage: use of stainless steel thumbtacks to obtain hemostasis. AM J OBSTET GYNECOL 1990;162:452).

We obtained radiographs after surgery in a patient whom we treated in November 1987 (Figs. 1 and 2). At that time, she was a 42-year-old gravida 14, para 13-0-12, white woman at 35 weeks' gestation with a 2 cm stage IB (International Federation of Gynecology and Obstetrics) squamous carcinoma of the cervix. A low vertical cesarean section and radical hysterectomy with bilateral salpingo-oophorectomy and pelvic and paraaortic lymphadenectomy were performed. When the retroperitoneal spaces were opened, massive pelvic venous varicosities were encountered. These vessels were fastidiously avoided, but retractor trauma resulted in presacral bleeding that could not be controlled with pressure or suture ligation. Three thumbtacks were sterilized and carefully placed in the presacral area with

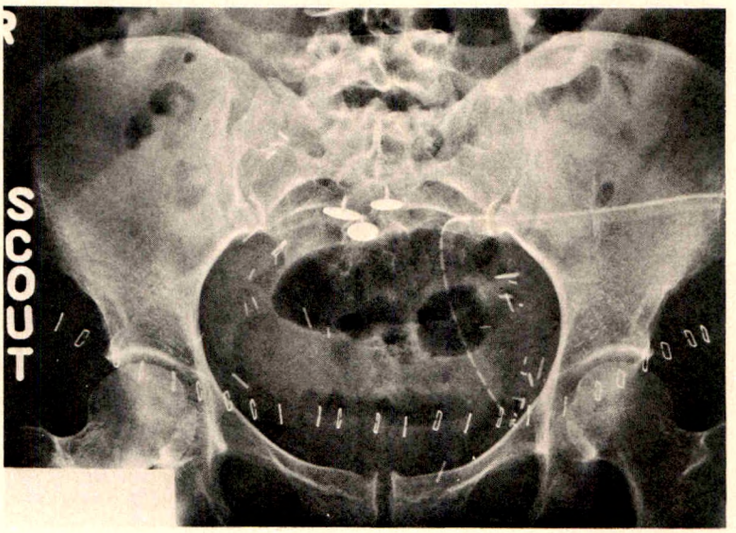

Fig. 1. Kidney and upper bladder radiograph shows thumbtacks in anterior sacrum.

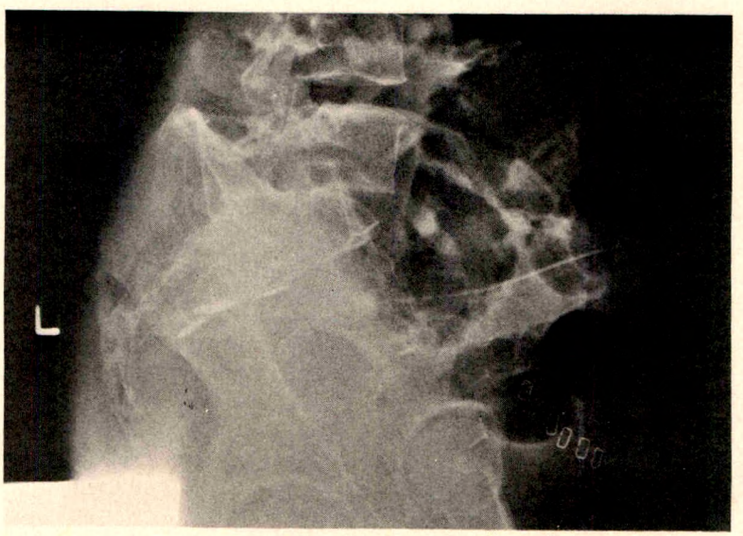

Fig. 2. Lateral radiograph shows thumbtacks in anterior sacrum.

pressure from a Kelly clamp. Hemostasis was achieved rapidly. This patient recovered uneventfully despite an operative blood loss of 10,000 ml. She has been free of cancer for 3 years and has no symptoms that can be attributed to the thumbtacks.

As a surgeon who is familiar with such cases,[1] I heartily endorse the timely use of sterile thumbtacks in the case of massive presacral bleeding.

The importance of the postcoital test

To the Editors: I read with interest the article by Griffith and Grimes (Griffith CS, Grimes DA. The validity of the postcoital test. Am J Obstet Gynecol 1990; 162:615-20.) on the validity of the postcoital test. They point out to the reader the problems in interpretation of previous articles in the literature: variation existed in standardization for the interval after intercourse, definition of an abnormal postcoital test, timing in the cycle of the postcoital test, and degree of investigation of other factors that could lead to infertility.

The emphasis of these shortcomings should certainly make the reader at least question some of the previous dogmatic statements that were made about the clinical importance of the postcoital test and should encourage clinicians and researchers to perform prospective randomized investigations to determine whether performance of this test is a waste of time or money.

However, instead of merely highlighting the caveats, the authors proceeded to use the same discordant studies to leave the reader with the impression that the postcoital test has poor validity as a diagnostic test for infertility and therefore to encourage the clinician to abandon the test, rather than to refine the postcoital examination and then assess its clinical importance. They suggest, in fact, that at least $50,000,000 is wasted each year on a test with poor validity.

We previously presented data concerning the importance of the use of follicular maturation studies to be certain of proper timing of the examination and to be sure that poor quality mucus is not related to failure to form a mature follicle (inadequate estrogen effect) or premature luteinization (adverse progesterone effect).[1] We, like Hull et al.,[2] define abnormal as the absence of progressively moving sperm in the mucus 8 to 12 hours after intercourse. In one study of 70 patients whose only apparent infertility problem was a cervical factor, only 2 of 20 patients (10%) conceived when the test was not corrected compared with 37 of 50 patients (74%) in whom at least some sperm with progressive forward motion were noted in the mucus.[3]

One problem with the conclusions from the ethinyl-estradiol-human menopausal gonadotropin study was that even though mature follicles were demonstrated at the time of the postcoital tests, the possibility existed that hyperstimulation might have been responsible for the pregnancy rather than improvement of the sperm-mucus interaction. Recently, however, we presented data at the Seventh World Congress on Human Reproduction in Helsinki, Finland, which were based on nonstimulated cycles with 0 moving sperm. After intercourse there was only a 3.9% pregnancy rate per cycle compared with 21.2% with properly timed intrauterine insemination.

I write this letter to caution the reader not to abandon the postcoital test but to strive to be careful about potential pitfalls in misinterpretation and to be open-minded about the importance of the test. Until the authors or some other researchers present clear prospective data that negate the clinical importance of this test, I believe that conclusions about the invalidity of the test, which are based on other studies that lack standardization, are in themselves invalid.

Reply

To the Editors: Dr. Check seems to agree with our major points, yet he reaches a different conclusion than we did. He criticizes our having "proceeded to use these same discordant studies" for assessment of the validity of the postcoital test. Regrettably, these are the best available data. Quantitative evaluation of the validity of this test was long overdue.

We agree about the importance of good cervical mucus. As we stated in our article, we restricted our analysis to only those patients with good cervical mucus to control for this potentially distorting factor. Dr. Check's other comments about the ethinyl-estradiol-human menopausal gonadotropin study and the data that were presented in Helsinki do not relate to validity.

Dr. Check's final paragraph is puzzling. He agrees that there are "potential pitfalls," about which one must be "careful." All the studies that we analyzed were prospective in design; taken together, they suggest that the test lacks validity. He neither disputes our calculations nor offers other studies that contradict our findings. However, he believes that no conclusions can be drawn. Is this being "open-minded about the importance of the test?"

Within several years of its introduction, the enzyme-linked immunosorbent assay test for the human immunodeficiency virus was shown to be highly sensitive and specific as well as clinically useful.[1, 2] In contrast, the postcoital test has been used widely for more than 120 years, yet objective evidence of its validity, reliability, and utility is lacking. If millions of tests and a century of experience have not demonstrated its value, what is the probability that a few more decades of use will?

When we choose tests and procedures, we must be sure that they are worth the expense, pain, and inconvenience that they cause. In a discussion of protection of the "medical commons" from "overgrazing" by tests and procedures of no value or of undetermined value, the Dean of the Harvard School of Public Health[3] cited many examples of practices that were once widely used but have now disappeared. Because they remained on the "medical commons" too long, valuable health resources were squandered. Widespread postcoital testing draws money and personnel away from other areas of medicine. If these other areas of medicine are more important, then the testing has a negative effect on public health.

First-trimester transvaginal ultrasonographic screening: Incidence of structural anomalies

To the Editors: I read with interest the article "Transvaginal ultrasonographic diagnosis in the first trimester" by Cullen et al. (Cullen MT, Green J, Whetham J, Salafia C, Gabrielli S, Hobbins J. AM J OBSTET GYNECOL 1990;163:466-76). The 33 embryos identified as having structural anomalies in the 622 patients studied makes the incidence of structural anomalies 5.3%, not 0.5% as the authors state. This percentage now becomes unusually high rather than the "surprisingly low" incidence they cite in their discussion. How would the argument change in the light of the correct statistics? What could be the reason for scanning a low-risk population and obtaining such a remarkably high incidence of anomalies?

The last sentence of the article, in which the authors state, "Prenatal diagnosis of structural anomalies will move into the first trimester," may be a premature consideration.[1] Structural anomalies revolving around secretion, passage, or absorption of systemic fluids (e.g., cerebrospinal fluid, urine, or swallowed amniotic fluid) or others such as microcephalus, agenesis of corpus callosum, or cleft palate may not be detected during the first trimester, and the list is long.

Therefore I would not move ultrasonographic diagnosis of structural anomalies into the first trimester with the knowledge that many anomalies will develop during the second trimester.

Shraga Rottem, MD, DSc
Department of Obstetrics and Gynecology, Rambam Medical Center, 31096 Haifa, Israel

REFERENCE

1. Rottem S, Bronshtein M. Transvaginal sonographic diagnosis of congenital anomalies between 9 weeks and 16 weeks, menstrual age. JCU 1990;18:307-14.

Reply

To the Editors: Dr. Rottem has correctly pointed out an error in decimal placement. Twenty-two of the 33 fetal anomalies (66%) occurred in patients with a high risk of congenital anomaly. The remaining 11 were from a relatively low-risk population. This incidence is lower than would be expected for the general population at term and lower than our expectations, when the higher incidence of aneuploidy in the first trimester is considered.

Dr. Rottem is concerned that by moving prenatal diagnosis into the first trimester some anomalies may be missed. We emphasized in the manuscript the possible limitations of early ultrasonographic diagnosis and cited specific examples. However, this should not stop investigators from attempting early diagnosis. We certainly do not advocate a single first-trimester transvaginal examination as a final screening test.

Metabolic effects of danazol

To the Editors: I was interested to read the report entitled "Insulin-dependent diabetes mellitus associated with danazol" (Seifer DB, Freedman LN, Cavender JR, Baber RA. AM J OBSTET GYNECOL 1989;162:474-5.) Two points are worthy of mention.

First, the initial appearance of symptomatic hyperglycemia seems very likely to have been associated with danazol treatment, but the criteria for defining the patient's diabetes as "insulin-dependent" are not clear. The weight loss of 2 pounds is trivial and can be explained by day-to-day variation, and there is no mention of whether the patient had significant ketosis. Also, I note that she tested negative for islet cell antibodies. Moreover, true insulin-dependent diabetes can enter a "honeymoon phase" of improved glycemic control and reduced insulin requirements, but it would be very unusual for a patient to be able to stop taking insulin completely for several months, as in this case. The most

likely diagnosis in this patient is, in fact, *non*-insulin-dependent diabetes, which was presumably precipitated by danazol-induced insulin resistance and which was treated with insulin. It is probable that the patient would have responded to caloric restriction alone, which would not have been provided by the 2200-calorie diet that is designed for insulin-dependent diabetics.

The second point concerns the cause of danazol-induced hyperglycemia. Danazol causes postreceptor resistance to insulin, which is attributed to the androgenic properties of the drug.[1] Another possible action is through stimulation of glucagon secretion: danazol can induce hyperglucagonemia of the degree that is usually associated with glucagonoma.[2] This would both aggravate insulin resistance and stimulate insulin secretion, which, if the β-cell reserve were already compromised, might lead to exhaustion of insulin secretion and thus to non-insulin-dependent diabetes. A group of danazol-treated patients whom we described previously[2] were glucose-intolerant overall, and one patient had impaired glucose tolerance according to World Health Organization criteria. None of the patients in this group had any hyperglycemic symptoms, and the patient with impaired glucose tolerance reverted to normoglycemia after withdrawal of the drug. Stimulation of glucagon secretion may be an androgenic property, because oxymetholone can also cause "pseudoglucagonoma."[3]

In conclusion, it is clearly important to monitor glycemia in women who are being treated with danazol. Practitioners who prescribe this drug must also be aware that it can cause gross hyperglucagonemia. Recognition of this assocation may spare patients with danazol-induced "pseudoglucagonoma" from undergoing unnecessary and often invasive investigations.[4]

Reply

To the Editors: Although it is possible that our patient had non-insulin-dependent diabetes mellitus, we favored a diagnosis of insulin-dependent diabetes in light of 3+ ketones in the urine, which was accompanied by a random blood glucose level of 461 mg/dl and symptoms that required insulin for control. We acknowledge the possible presence of hyperglucagonemia as a result of danazol therapy, which may have exacerbated her symptoms.

Fetal subdural hematoma before labor

To the Editors: We are interested in the case report by Demir et al. (Demir RM, Gleicher N, Myers SA. Atraumatic antepartum subdural hematoma causing fetal death. Am J Obstet Gynecol 1989;160:619-20) but cannot agree with their statement that "No previous report has documented the presence of an atraumatic subdural hematoma resulting in fetal death before labor."

In 1984 we described 16 stillborn infants who had large, often bilateral, subdural hematomas.[1] The maternal histories suggested that fetal deaths occurred at a mean of 10 days before the macerated infants were delivered at gestations from 26 to 41 weeks. All mothers were immigrants from the Pacific Islands. We studied an additional 27 stillborn Pacific Islander infants with similar subdural hemorrhages that preceded the onset of labor and are still not certain of the cause.[2] There was no history of trauma or anticoagulation therapy and coagulation and platelet counts were normal in studies of the mothers and two similarly affected liveborn infants.[3]

Isoimmune thrombocytopenic purpura is one of the few coagulation disorders known to be associated with intracranial hemorrhages before delivery[4] and Demir et al. do not state whether this was excluded in their case by showing the absence of maternal antibodies specifically directed against paternal platelets. Demir et al. suggest that the hemorrhage was the cause of chronic hydrocephalus in their case in which a dilated third ventricle was consistent with obstruction of the aqueduct of Sylvius. We reported two cases of congenital hydrocephalus associated with fetal intracranial hemorrhage, and in one there was evidence that hemorrhage caused narrowing of the aqueduct.[5] Other infants showed effects of intrauterine blood loss such as edema or erythroblastosis.

We agree with Demir et al. that fetal subdural hematoma may be unrelated to birth trauma, but we are cautious about excluding other trauma on the basis of maternal history alone. There are many situations in which trauma to the mother might be denied subsequently and we speculate that the large number of cases in Pacific Islanders is caused by traditional forms of abdominal massage during pregnancy.[2] The condition is much less common in other populations in New Zealand but recently a 35-year-old European woman was delivered of an 800 gm male stillborn infant with a large subdural hematoma. We have seen liveborn infants with the consequences of similar hemorrhages and we agree that it is important for both medical and

legal reasons that birth trauma not be assumed to be the cause.

Reply

To the Editors: We appreciate the interest that Drs. Gunn and Becroft expressed in our earlier work. Whereas we were aware of the extensive experience these authors have in the field, editorial limitations did not allow us to fully acknowledge their contribution to the literature. Our interpretation of their work was that whereas they clearly had shown that such an entity as antepartum subdural hematoma exists, it had either not caused death antepartum or alternatively had caused death but was not diagnosed antepartum. Two of their works (references 2 and 5 of their letter) were not available to us at the time of our manuscript preparation. If we misinterpreted any of their earlier work, we apologize.

Unraveling the mysteries of vulval ulceration in human immunodeficiency virus–seropositive women

To the Editors: We believe that the case reported by Covino and McCormack (Covino JM, McCormack WM. Vulval ulcer of unknown etiology in a human immunodeficiency virus–infected woman: response to treatment with zidovudine. Am J Obstet Gynecol 1990;163:116-8) raises several points of interest.

First, although mention is made of oral aphthous ulceration, there is neither further comment on the significance of this nor apparent consideration of other diagnoses such as lichen planus or Crohn's disease. A review of the histopathology of the biopsy specimen with regard to such diagnoses may be worthwhile.

Second, immunocytochemical staining of the biopsy specimen by specific monoclonal antibodies to search for evidence of cytomegalovirus, herpes simplex virus, and human immunodeficiency virus (HIV) infection may have been useful. Cytomegalovirus has been reported as infecting the genital tract in HIV-seropositive women[1] and should be considered as a possible cause of ulceration in this patient. In a case reported from this unit,[2] extensive genital ulceration developed in a 23 year-old HIV-seropositive woman as a result of herpes simplex virus, which was originally sensitive to acyclovir but after 9 months continuous therapy became resistant with clinical deterioration. Zidovudine therapy led to almost complete resolution of this lesion; however, 15 months later a necrotizing proximal myopathy developed and zidovudine therapy ceased. The lesions recurred within 2 weeks, but treatment with intravenous foscarnet was commenced and the lesions completely resolved within 2 weeks. Inasmuch as foscarnet is active against cytomegalovirus, HIV, and herpes simplex virus, we believe that it may be a useful empirical therapy in such cases.

Third, there is no mention of other drugs that this patient may have been taking, for instance prophylaxis against *Pneumocystis carinii* pneumonia. Such a drug history is vital because a fixed drug eruption is an important differential diagnosis in this case.

Fourth, we agree that treatment of genital ulceration in HIV-infected patients is difficult. Zidovudine may have been successful because of its direct antiretroviral activity but also because of a stimulatory effect on the CD4 count. Thalidomide has also been reported to be effective in resistant mucosal ulcers associated with HIV, as have intralesional steroid injections.[3] However, the potential teratogenic effects of the former must be considered before its use in women of child-bearing age.

We believe that a combined team including dermatologists, gynecologists, and genitourinary physicians provides the best management in these difficult cases.

P.D. Kell, MD, and S.E. Barton, MD

Department of Genitourinary Medicine, St. Stephens Clinic, 369 Fulham Road, London, England SW10 9TH

3. Youle M, Hawkins D, Gazzard B. Thalidomide in hyperalgic pharyngeal ulceration in AIDS. Lancet 1990;1:1591.

Reply

To the Editors: We thank Drs. Kell and Barton for their comments regarding our article and for the opportunity to provide additional information regarding our patient.

First, histopathologic examination of the biopsy specimens from the vestibular ulcer disclosed only acute and chronic inflammation, granulation tissue, dysplasia, and condylomatous changes. Biopsy specimens of the oral aphthae were not obtained. There was no evidence of either lichen planus or Crohn's disease.

Second, we agree that immunocytologic staining of the biopsy specimens with specific monoclonal antibodies to search for cytomegalovirus, herpes simplex virus, and human immunodeficiency virus would have been useful. These reagents were not available to us at the time. Multiple specimens obtained from the ulcer were examined for viruses in tissue culture. All were negative for herpes simplex virus and cytomegalovirus. Similarly, histopathologic examination of the biopsy specimens disclosed no inclusions or other evidence of viral infection. Empiric treatment with acyclovir was not associated with healing of the ulcer. Although acyclovir-resistant herpes simplex virus can produce nonhealing genital ulcers, we are confident that our patient did not have herpes simplex virus.

Third, although the patient received brief courses of treatment with a number of medications after the development of the ulcer, she was not receiving medication before the development of the ulcer. Thus we do not believe that she had a fixed drug eruption.

Fourth, we agree that the favorable effect of zidovudine may have been a result of direct antiretroviral activity or of an increase in the effectiveness of the immune system as reflected by the CD4 cell count. However, the ulcer remained healed during the terminal phases of the patient's illness when the CD4 cell count had fallen to 0 cells/mm^3. We did not prescribe thalidomide or intralesional corticosteroids.

Finally, we agree that a multidisciplinary approach is needed for optimal management of difficult problems. We did obtain advice on the management of our patient from experts in many areas including colorectal surgery, gynecologic oncology, immunology, dermatology, and oral surgery.

Pelvic muscles and episiotomy

To the Editors: After analyzing the data from our research,[1] which involved measurement of the pelvic muscles with a reliable instrument, we question along with Drs. Thorp and Bowes (Thorp JM Jr, Bowes WA Jr. Episiotomy: Can its routine use be defended? Am J Obstet Gynecol 1989;160:1027-30) the routine use of episiotomy.

In our study, subjects were assessed at three intervals (prenatally, 6 to 8 weeks post partum, and 1 year post partum). None of the 22 vaginal birth subjects had episiotomies; 11 had intact perineums, three had first-degree labial lacerations, five had first-degree perineal lacerations, and three had second-degree perineal lacerations. At 1 year post partum ($n = 10$) there was significant improvement of the pelvic muscle function. It was concluded that the restitution of the pelvic muscles may occur over time and therefore episiotomy for prophylactic use in the prevention of pelvic muscle relaxation may not be defensible.

K.R. Cosner, CNM, MSN, Molly C. Dougherty, PhD, and Kevin R. Bishop, ARNP
Box J-197, JHMHC, College of Nursing, Gainesville, FL 32610

REFERENCE

Reply

To the Editors: We appreciate the interest of Cosner et al. in our article. The data mentioned in their letter are of great interest inasmuch as they report a 1-year follow-up examination. The long-term effect of the method of delivery (including the use of episiotomy) on neuromuscular function of the perineum, rectum, and pelvis is yet to be adequately determined. Only studies with long-term follow-up of the patients will answer this question.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1991 issues from the Publisher, at a cost of $61.00 ($84.00 international) for Vol. 164 (January-June) and Vol. 165 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact Mosby–Year Book, Inc., Subscription Services, 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, USA; phone (800) 325-4177, ext. 4351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

HIGH-RISK OBSTETRICS

The Saudi Arabian Oil Company's (SAUDI ARAMCO) Medical Services Organization in Saudi Arabia is interviewing for experienced Obstetricians/Gynecologists with subspecialty in maternal fetal medicine to join an Obstetrical staff of 16.

With a patient population of approximately 200,000, Saudi Aramco's medical facilities provide comprehensive medical care to our employees and their dependents. The Dhahran Health Center, recently expanded to 483-beds, offers all major specialty services as well as sub-specialties and functions as a referral center. American Board Certification and two years' experience after residency required. Strong leadership qualities and experience in both a professional and administrative capacity are preferred.

As a Saudi Aramco employee, you will receive a competitive base compensation package, as well as an expatriate premium. Additional benefits include noncontributory group life insurance, company-matched savings, free medical care at Saudi Aramco's hospital and clinics, housing inside a company community, and extensive recreation facilities and activities. Your eligible children will be enrolled in company schools, comparable to U.S. private schools. There are up to 13 company holidays annually, and you will be eligible for 36 calendar days of vacation, with round trip airfares to the U.S. or Canada for you and your family.

Investigate these truly unique opportunities by calling **OUR 24 HOUR, 7 DAYS PER WEEK TOLL-FREE NUMBER LISTED BELOW.**

Lexington, Kentucky 40536-0084

THE UNIVERSITY OF KENTUCKY IS AN AFFIRMATIVE ACTION, EQUAL OPPORTUNITY EMPLOYER AND ACTIVELY SEEKS THE CANDIDACY OF MINORITIES AND WOMEN.

The Women and Infants Hospital of Rhode Island is seeking a candidate for the position of Maternal/ Fetal Specialist. The job responsibilities include: patient care, teaching, research and assistance in divisional administration.

The minimum requirements are: active candidacy for or certification by the American Board of Obstetrics and Gynecology, active candidacy for or certification by the ABOG subspecialty of Maternal/Fetal Medicine, qualification as an Assistant Professor of Obstetrics and Gynecology at Brown University, and proven teaching abilities. Rank and remuneration will be commensurate with experience and qualifications.

The Women and Infants Hospital of Rhode Island is an Equal Opportunity/Affirmative Action employer and actively solicits applications from minority and protected groups. Interested individuals should send an application and curriculum vitae to:

Marshall Carpenter, MD
Director, Maternal/Fetal Medicine
Chairman, Search Committee
101 Dudley Street
Providence, RI 02905

Applications are expected by April 1, 1991. Screening will begin on that date and will continue until a successful candidate has been identified or the search is closed.

JOHNS HOPKINS HEALTH SYSTEM medical group seeks full-time Director of Obstetrics and Gynecology for established office in Baltimore. Competitive salary and benefits plan (including professional liability insurance) offered. This blend of ambulatory and hospital obstetrics and gynecology with departmental administrative and quality assurance responsibilities is an opportunity for clinicians ready to assume managerial responsibilities. Must be board certified or active candidate, and eligible for Maryland license and DEA certificate. Position to be filled by mid-1991. Equal Employment Opportunity Employer. Send current curriculum vitae to: Recruiting Coordinator; Office of Medical Affairs; Wyman Park Medical Associates; 3100 Wyman Park Drive; Baltimore, Maryland 21211.

GYN ONCOLOGIST

New Hanover Regional Medical Center, located in beautiful, historic, oceanside Wilmington, North Carolina is seeking a board certified or active candidate Gyn oncologist, preferably with academic experience tc assist four other full-time faculty in supervising the training of residents and students. New Hanover Regional Medical Center is a 500 bed major referral hospital for Southeastern North Carolina with Ob/Gyn and other graduate medical education programs affiliated with the University of North Carolina School of Medicine. The Ob/Gyn program is approved for twelve residents and full-time faculty are supported by faculty visits from UNC-Chapel Hill as well as an enthusiastic private attending staff. Teaching responsibilities also include medical students from the University of North Carolina at Chapel Hill. Successful candidate will be eligible for tenure track appointment at UNC School of Medicine. Academic appointment and salary dependent on training and experience. Please submit curriculum vitae and references to:

Chairman, Search Committee in Ob/Gyn
Area Health Education Center
New Hanover Regional Medical Center
2131 South 17th Street
Wilmington, North Carolina 28402

with article reprints from Mosby-Year Book periodicals

Article reprints are your best means of distributing the information published in Mosby-Year Book's medical, dental, and nursing periodicals. These papers will enhance the value of your information programs.

Not just for authors, reprints are an effective tool for health care professionals, sales and marketing staffs, and advertisers.

Use reprints to:

- Train and educate your sales and marketing staff
- Support your seminar topic
- Inform your health care staff of new developments
- Reach your product users with vital information

Article reprints. . . another valuable service from Mosby-Year Book.

Orders (minimum of 100 copies) of all previous and future articles in Mosby-Year Book periodicals are available from the Publisher.

21- and 28-day regimens

ORTHO-NOVUM® 777 Tablets

norethindrone/ethinyl estradiol

Low incidence of androgenic side effects

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

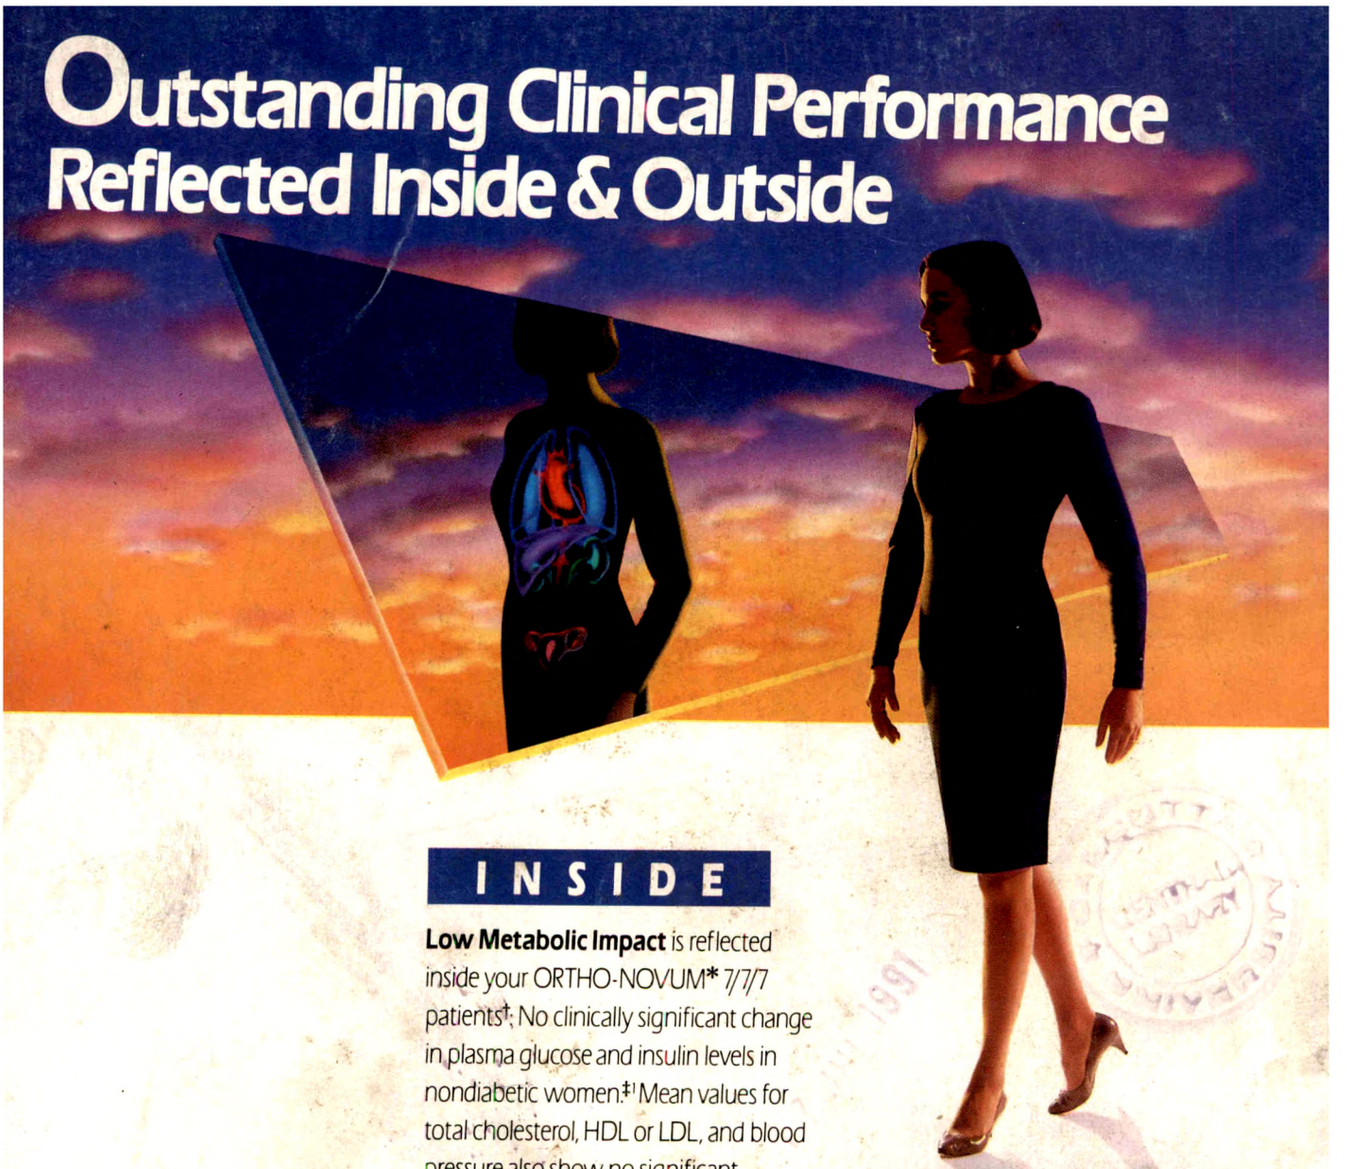
CONTRAINDICATIONS: Oral contraceptives should not be used in women who currently have the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Carcinoma of the endometrium or other known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Cholestatic jaundice of pregnancy or jaundice with prior pill use. 8. Hepatic adenomas or carcinomas. 9. Known or suspected pregnancy.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, and gallbladder disease, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this brief summary is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this brief summary epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of a disease, namely a *ratio* of the incidence of a disease among oral contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the *difference* in the incidence of disease between oral contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods. 1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. a. Myocardial Infarction. An increased risk of myocardial infarction has been associated with oral contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers, especially in those 35 years of age and older among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in WARNINGS). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors. b. Thromboembolism. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to non-users to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease associated with oral contraceptives is not related to length of use and disappears after pill use is stopped. A two- to four-fold increase in relative risk of post-operative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate postpartum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four weeks after delivery in women who elect not to breast feed. c. Cerebrovascular diseases. Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and non-users, for both types of strokes, and smoking interacted to increase the risk of stroke. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for non-smokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women. d. Dose-related risk of vascular disease from oral contraceptives. A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the activity of the progestogen used in the contraceptive. The activity and amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral contraceptive agents should be started on preparations containing 0.035 mg or less of estrogen. e. Persistence of risk of vascular disease. There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral contraceptive formulations containing 50 micrograms or higher of estrogens. 2. ESTIMATES OF MORTALITY FROM CONTRACEPTIVE USE. One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is low and below that associated with childbirth. However, smokers 35 and older and non-smokers 40 and older who use oral contraceptives have a significant increase in mortality higher than those using other methods of birth control. These facts must be weighed in conjunction with failure rates for other methods and the risk associated with subsequent pregnancy. 3. CARCINOMA OF THE REPRODUCTIVE ORGANS. Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. While there are conflicting reports most studies suggest that use of oral contraceptives is not associated with an overall increase in the risk of developing breast cancer. Some studies have reported an increased relative risk of developing breast cancer, particularly at a younger age. This increased relative risk appears to be related to duration of use. Some studies suggest that oral contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. 4. HEPATIC NEOPLASIA. Benign hepatic adenomas are associated with oral contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use especially with oral contraceptives of higher dose. Rupture of benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral contraceptive users. However, these cancers are rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral contraceptive users approaches less than one per million users. 5. OCULAR LESIONS. There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia, papilledema, or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately. 6. ORAL CONTRACEPTIVE USE BEFORE OR DURING EARLY PREGNANCY. Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. The majority of recent studies also do not indicate a teratogenic effect, particularly in so far as cardiac anomalies and limb reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods pregnancy should be ruled out before continuing oral contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral contraceptive use should be discontinued until pregnancy is ruled out. 7. GALLBLADDER DISEASE. Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral contraceptive formulations containing lower hormonal doses of estrogens and progestogens. 8. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. This effect has been shown to be directly related to estrogen dose. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the non-diabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects prediabetic and diabetic women in particular should be carefully monitored while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see WARNINGS 1a and 1d), changes in serum triglycerides and lipoprotein levels have been reported in oral contraceptive users. 9. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in women taking oral contraceptives, and this increase is more likely in older oral contraceptive users and with extended duration of use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing progestational activity. Women with a history of hypertension or hypertension-related diseases, or renal disease, should be encouraged to use another method of contraception. If women elect to use oral contraceptives, they should be monitored closely and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension between former and never users. 10. HEADACHE. The onset or exacerbation of migraine or development of headache with a new pattern which is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause. 11. BLEEDING IRREGULARITIES. Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. Non-hormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent. 12. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. **PRECAUTIONS:** 1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine and liver function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3, increased norepinephrine-induced platelet aggregability. b. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radio-immunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See WARNINGS section. 10. PREGNANCY. Pregnancy Category X. See CONTRAINDICATIONS and WARNINGS sections. 11. NURSING MOTHERS. Small amounts of oral contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child. **INFORMATION FOR THE PATIENT: See Patient Package Insert.**

ADVERSE REACTIONS: An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS section). Thrombophlebitis and venous thrombosis with or without embolism. Arterial thromboembolism. Pulmonary embolism. Myocardial infarction. Cerebral hemorrhage. Cerebral thrombosis. Hypertension. Gallbladder disease. Hepatic adenomas or benign liver tumors. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea. Vomiting. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Amenorrhea. Temporary infertility after discontinuation of treatment. Edema. Melasma which may persist. Breast changes: tenderness, enlargement, secretion. Change in weight (increase or decrease). Change in cervical erosion and secretion. Diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: Pre-menstrual syndrome. Cataracts. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. Acne. Changes in libido. Colitis.



OVERDOSAGE: Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea and withdrawal bleeding may occur in females.

Revised 9/89

ORTHO PHARMACEUTICAL CORPORATION
Raritan, New Jersey 08869

ORTHO

Outstanding Clinical Performance Reflected Inside & Outside

INSIDE

Low Metabolic Impact is reflected inside your ORTHO-NOVUM* 7/7/7 patients†: No clinically significant change in plasma glucose and insulin levels in nondiabetic women.‡[1] Mean values for total cholesterol, HDL or LDL, and blood pressure also show no significant change.§

Excellent Cycle Control is another reflection of outstanding performance with ORTHO-NOVUM 7/7/7. You can expect low discontinuation rates due to breakthrough bleeding, spotting, and amenorrhea.

OUTSIDE

Low Incidence of Androgenic Side Effects—such as acne, oily skin, or hirsutism—is a visible reflection that your patients may notice; another is no clinically significant change in mean body weight. Inside and outside, the outstanding performance of ORTHO-NOVUM 7/7/7 is also an excellent reflection on you.

Low incidence of androgenic side effects

*Trademark

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

‡Oral contraceptives have been shown to cause a decrease in glucose tolerance in a significant percentage of users. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents.

§An increase in blood pressure has been reported in women taking oral contraceptives.

FEMSTAT® PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

So effective, it works with 3-day therapy.

SYNTEX

SYNTEX LABORATORIES, INC
PALO ALTO, CA 94304

Committed to the OB/GYN and women's healthcare

FEMSTAT PREFILL

(butoconazole nitrate) VAGINAL CREAM 2%

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

THE OC TO START WITH BECAUSE SHE'LL STAY WITH IT

IN BRIEF:
TRIPHASIL® — 6 brown tablets containing 0.050 mg levonorgestrel with 0.030 mg ethinyl estradiol; 5 white tablets containing 0.075 mg levonorgestrel with 0.040 mg ethinyl estradiol; 10 light-yellow tablets containing 0.125 mg levonorgestrel with 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day regimen) — Triphasic regimen.

Indications and Usage — TRIPHASIL® is indicated for the prevention of pregnancy in women who elect to use oral contraceptives (OC's) as a method of contraception.

Contraindications — OC's should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep-vein thrombophlebitis or thromboembolic disorders. 3. Cerebral-vascular or coronary-artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed abnormal genital bleeding. 7. Known or suspected pregnancy (see Warning No. 5). 8. Benign or malignant liver tumor which developed during use of OC's or other estrogen-containing products.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.
The use of oral contraceptives is associated with increased risk of several serious conditions, including thrombo-embolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners pre-scribing oral contraceptives should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems* — An increased risk of thromboembolic and thrombotic disease associated with use of OC's is well established. Three principal studies in Great Britain and 3 in the U.S. have demonstrated increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of OC's are 4 to 11 times more likely than nonusers to develop these diseases without evident cause.

CEREBROVASCULAR DISORDERS — In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than nonusers and the risk of thrombotic stroke was 4 to 9.5 times greater in users than in nonusers.

MYOCARDIAL INFARCTION (MI) — An increased risk of MI associated with the use of OC's has been reported, con-firming a previously suspected association. These studies, conducted in the UK, found, as expected, that the greater the number of underlying risk factors for coronary-artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of pre-eclamptic toxemia) the higher the risk of develcping MI, regardless of whether the patient was an OC user or not. OC's, however, were found to be a clear additional risk factor. In terms of relative risk, it has been estimated that OC users who do not smoke (smoking is considered a major predisposing condition to MI) are about twice as likely to have a fatal MI as nonusers who do not smoke. OC users who are also smokers have about a 5-fold increased risk of fatal MI compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, amount of smoking is also an important factor. In determining importance of these relative risks, however, baseline rates for various age groups must be given serious consideration. Importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; quite likely the same synergistic action exists, but perhaps to a lesser extent.

RISK OF DOSE — In an analysis of data derived from several national adverse-reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to dose of estrogen in OC's. Preparations containing 100 mcg or more of estrogen were associated with higher risk of thromboembolism than those containing 50-80 mcg. Their analysis did suggest, however, that quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the U.S.

ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES — A large prospective study carried out in the UK estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of OC's according to age, smoking habits, and duration of use. Overall excess death rate annually from circulatory diseases for OC users was estimated to be 20 per 100,000 (ages 15-34 — 5/100,000; ages 35-44 — 33/100,000; ages 45-49 — 140/100,000), risk being concentrated in older women, in those with long duration of use and in cigarette smokers. It was not possible, however, to examine interrelationships of age, smoking, and duration of use, nor to compare effects of continuous vs. intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for 5 or more years are available, it is not possible to assess magnitude of relative risk for this younger group. Available data from a variety of sources have been analyzed to estimate risk of death associated with various methods of contraception. Estimates of risk of death for each method include combined risk of contraceptive method (e.g., thromboembolic and thrombotic disease in the case of OC's) plus risk attributable to pregnancy or abortion in event of method failure. This latter risk varies with effectiveness of method. The study concluded that mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of OC's in women over 40 who smoke. Lowest mortality is associated with condom or diaphragm backed up by early abortion. Risk of thromboembolic and thrombotic disease associated with OC's increases with age after about 30 and, for MI, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of pre-eclamptic toxemia, and especially cigarette smoking. Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A 4- to 6-fold increased risk of postsurgery thromboembolic complications has been reported in OC users. If feasible, OC's should be discontinued at least 4 weeks before surgery of a type associated with increased risk of thromboembolism or prolonged immobilization.

PERSISTENCE OF RISK OF VASCULAR DISORDERS — Findings from one study in Britain involving cerebrovascular disease and another in the U.S. concerning MI suggest an increased risk of these conditions in users of OC's persists after discontinuation of the OC's. In the British study, risk of cerebrovascular disease remained elevated in former OC users for at least 6 years after discontinuation. In the U.S. study, increased risk of MI persisted for at least 9 years in women 40 to 49 years old who had used OC's for 5 or more years. Findings in both studies require confirmation since they are inconsistent with other published information.

2. *Ocular Lesions* — There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with use of OC's. Discontinue OC's if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal-vascular lesions, and institute appropriate diagnostic and therapeutic measures.

3. *Carcinoma* — Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in OC's, have been noted to increase incidence of mammary nodules, benign and malignant, in dogs. In humans, 3 case-control studies have reported an increased risk of endometrial carcinoma associated with prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on OC's. Of cases found in women without predisposing risk factors (e.g., irregular bleeding at the time OC's were first given, polycystic ovaries), nearly all occurred in women who had used a sequential OC. These are no longer marketed. No evidence has been reported suggesting increased risk of endometrial cancer in users of conventional combination or progestogen-only OC's. Several studies have found no increase in breast cancer in women taking OC's or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women on OC's, found an excess risk in subgroups of OC users with documented benign breast disease. Reduced occurrence of benign breast tumors in users of OC's has been well documented. In summary, there is at present no confirmed evidence from human studies of increased risk of cancer associated with OC's. Close clinical surveillance of all women on OC's is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or with breast nodules, fibrocystic disease, or abnormal mammograms should be monitored with particular care if they elect to use OC's.

4. *Hepatic Tumors* — Benign hepatic adenomas have been found to be associated with use of OC's. One study showed that OC's with high hormonal potency were associated with higher risk than lower potency OC's. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users. Two studies relate risk with duration of use of OC's, the risk being much greater after 4 or more years' use. While hepatic adenoma is rare, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. A few cases of hepatocellular carcinoma have been reported in women on OC's. Relationship of these drugs to this type of malignancy is not known.

5. *Use in or Immediately Preceding Pregnancy. Birth Defects in Offspring; and Malignancy in Female Offspring* — Use of female sex hormones — both estrogenic and progestational agents — during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have increased risk of developing in later life a form of vaginal or cervical cancer ordinarily extremely rare. This risk has been estimated to be of the order of 1 in 1,000 exposures or less. Although there is no evidence now that OC's further enhance risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use OC's. Furthermore, 30 to 90% of such exposed women have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with use of other estrogens, it cannot be presumed they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with use of sex hormones, including OC's, in pregnancy. One case-control study estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (OC's, hormonal withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some exposures involved only a few days. Data suggest that risk of limb-reduction defects in exposed fetuses is somewhat less than 1 in 1,000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OC's. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OC's is unknown. It is recommended that, for any patient who has missed 2 consecutive periods, pregnancy should be ruled out before continuing OC's. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at time of first missed period, and further use of OC's should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus, and advisability of continuation of the pregnancy should be discussed. It is also recommended that women who discontinue OC's with intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend 3 months, although no precise information is available on which to base this. The administration of progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy.

6. *Gallbladder Disease* — Studies report increased risk of surgically confirmed gallbladder disease in users of OC's and estrogens. In one study, increased risk appeared after 2 years' use and doubled after 4 or 5 years' use. In one of the other studies, increased risk was apparent between 6 and 12 months' use.

7. *Carbohydrate and Lipid Metabolic Effects* — Decrease in glucose tolerance has been observed in a significant percentage of patients on OC's. For this reason, prediabetic and diabetic patients should be carefully observed while on OC's. Increases in triglycerides and total phospholipids have been observed in patients on OC's. Three studies were performed with Triphasil and no significant alterations in lipid metabolism were noted except for a slight increase in triglyceride levels in 1 study. Clinical significance of these findings remains to be defined.

8. *Elevated Blood Pressure* — Increase in blood pressure has been reported in patients on OC's. In some women, hypertension may occur within a few months of beginning OC's. In the 1st year of use, prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. Prevalence in users increases, however, with longer exposure, and in the 5th year of use is 2½ to 3 times the reported prevalence in the 1st year. Age is also strongly correlated with development of hypertension in OC users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure on OC's. Hypertension that develops as a result of taking OC's usually returns to normal after discontinuing the drug.

9. *Headache* — Onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of OC's and evaluation of the cause.

10. *Bleeding Irregularities* — Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing OC's. In breakthrough bleeding, as in all cases of irregular vaginal bleeding, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or change to another OC may solve the problem. Changing to an OC with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary, since this may increase risk of thromboembolic disease. Women with past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuing OC's. Women with these preexisting problems should be advised of this possibility and encouraged to use other methods. Post-use anovulation, possibly prolonged, may also occur in women without previous irregularities.

11. *Ectopic Pregnancy* — Ectopic as well as intrauterine pregnancy may occur in contraceptive failures.

12. *Breast-feeding* — OC's given in the postpartum period may interfere with lactation and decrease quantity and quality of breast milk. Furthermore, a small fraction of the hormones in OC's has been identified in the milk of mothers on OC's; effects, if any, on the breast-fed child have not been determined. If feasible, defer OC's until infant has been weaned.

Precautions — GENERAL — 1. A complete medical and family history should be taken prior to initiation of OC's. Pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Pap smear and relevant laboratory tests. As a general rule OC's should not be prescribed for longer than 1 year without another physical examination and Pap smear. 2. Under influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while on OC's should stop OC's and use an alternate method to try to determine whether the symptom is drug-related. 4. OC's may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while on OC's. If jaundice develops, OC's should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution. 7. OC users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. Clinical significance is undetermined. 8. Serum folate levels may be depressed by OC's. Since the pregnant woman is predisposed to development of folate deficiency and incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping OC's, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. 9. The pathologist should be advised of OC therapy when relevant specimens are submitted. 10. Certain endocrine- and liver-function tests and blood components may be affected by estrogen-containing OC's. a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total-thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test.

Information for the Patient — See Patient Package Labeling.

Drug Interactions — Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin and tetracycline.

Carcinogenesis — See Warnings section for information on carcinogenesis.

Pregnancy — Category X. See Contraindications, Warnings.

Nursing Mothers — See Warnings.

Adverse Reactions — An increased risk of these serious adverse reactions has been associated with use of OC's (see Warnings): thrombophlebitis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, cerebral hemorrhage, hypertension, gallbladder disease, benign hepatomas, congenital anomalies. There is evidence of an association between the following conditions and use of OC's although additional confirmatory studies are needed: mesenteric thrombosis, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been reported in patients on OC's and are believed to be drug-related. Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10 percent or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea, amenorrhea during and after treatment, temporary infertility after discontinuance of treatment; edema; chloasma or melasma which may persist; breast changes: tenderness, enlargement, and secretion; change in weight (increase or decrease); change in cervical erosion and cervical secretion; possible diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; increase in size of uterine leiomyomata; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening), intolerance to contact lenses. The following adverse reactions have been reported in users of OC's, and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, hemolytic uremic syndrome.

Acute Overdose — Serious ill effects have not been reported following acute ingestion of large doses of OC's by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Dosage and Administration — For maximum contraceptive effectiveness, Triphasil must be taken exactly as directed and at intervals not over 24 hours. (If Triphasil is first taken later than first day of first menstrual cycle of medication or postpartum, contraceptive reliance should not be placed on it until after the first 7 consecutive days of use. Possibility of ovulation and conception prior to initiation of medication should be considered.)
Any time patient misses 1 or 2 brown, white or light-yellow tablets, she should also use another contraceptive method until she has taken a tablet daily for 7 consecutive days. For full details on dosage and administration see prescribing information in package insert.

Cell adhesion molecules and the regulation of development 939

Bruce A. Cunningham, PhD

New York, New York

Cell adhesion molecules are cell surface glycoproteins that are dynamically expressed throughout development and can regulate other developmental processes.

Periovulatory calcium channel blockade enhances reproductive performance in an animal model for endometriosis-associated subfertility 949

Alex Steinleitner, MD, Hovey Lambert, PhD, Mariluz Suarez, BS, Nurys Serpa, BS, Beverly Robin, BS, and Bernard Cantor, MD

Miami Beach, Florida

Periovulatory calcium channel blockade enhanced fertilization in an animal model for endometriosis.

Macrophage-conditioned media enhance endometrial stromal cell proliferation in vitro 953

David L. Olive, MD, Iris Montoya, BS, Robert M. Riehl, PhD, and Robert S. Schenken, MD

San Antonio, Texas

Macrophage-conditioned media, when added to endometrial stromal cell culture, confer a state of competence on the cells and allow stimulation of cell growth progression factors such as estradiol and insulin.

Astrocytes within the hypothalamic arcuate nucleus contain estrogen-sensitive peroxidase, bind fluorescein-conjugated estradiol, and may mediate synaptic plasticity in the rat 959

David L. Keefe, MD, David S. Michelson, S.H. Lee, MD, and Frederick Naftolin, MD, DPhil

New Haven, Connecticut

Astrocytes within the hypothalamic arcuate nucleus contain estrogen-sensitive peroxidase activity, bind fluorescein-conjugated estradiol, and may mediate synaptic plasticity in the rat.

The role of the placenta in nutrition of the human fetus 967

Henning Schneider, MD

Berne, Switzerland

Principles of human placental transport mechanisms are discussed with emphasis on results obtained by dual in vitro perfusion of an isolated cotyledon.

Pulmonary injury associated with antepartum pyelonephritis: Can patients at risk be identified? 974

Craig V. Towers, MD, Carol M. Kaminskas, MD, Thomas J. Garite, MD, Michael P. Nageotte, MD, and Wendy Dorchester, MPH

Orange and Long Beach, California

Certain treatment modalities that are used to manage antepartum pyelonephritis may increase the risk for developing the rare but serious disorder of pulmonary injury.

Randomized comparative trial of indomethacin and ritodrine for the long-term treatment of preterm labor 981

Richard E. Besinger, MD, Jennifer R. Niebyl, MD, William G. Keyes, MD, PhD, and Timothy R.B. Johnson, MD

Baltimore, Maryland

Long-term oral indomethacin, which was as effective as β-sympathomimetics in the treatment of preterm labor, resulted in fewer maternal side effects but an increased risk of neonatal pulmonary hypertension.

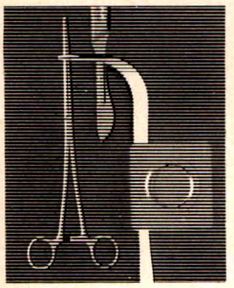
CEFOTAN® IM/IV



(cefotetan disodium)

In intra-abdominal and gynecologic infection due to indicated organisms

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri,* and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli.*
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli.*
Gynecologic infections caused by *Staphylococcus aureus** (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis, Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,* and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species*).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae**), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus.**
*Efficacy for this organism in this organ system was studied in fewer than ten infections.

Specimens for bacteriological examination should be obtained in order to isolate and identify causative organisms and to determine their susceptibilities to cefotetan. Therapy may be instituted before results of susceptibility studies are known; however, once these results become available, the antibiotic treatment should be adjusted accordingly.

In cases of confirmed or suspected gram-positive or gram-negative sepsis or in patients with other serious infections in which the causative organism has not been identified, it is possible to use CEFOTAN concomitantly with an aminoglycoside. Cefotetan combinations with aminoglycosides have been shown to be synergistic in vitro against many Enterobacteriaceae and also some other gram-negative bacteria. The dosage recommended in the labeling of both antibiotics may be given and depends on the severity of the infection and the patient's condition.

NOTE: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycosidic antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile.* Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment or poor nutritional state, the elderly and patients with cancer. Prothrombin times should be monitored in patients at risk and exogenous vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc.) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: Although to date nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels by Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approximately 8-16 times the usual adult human dose) on days 6-35 of life (thought to be

developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approximately 2-4 times the usual human dose) only 1 of 10 treated animals was affected, and the degree of degeneration was mild.

Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies, the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5% of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4% of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2% of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2% of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than 1.0% of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500). During postmarketing experience with CEFOTAN, anaphylactic reactions and transient thrombocytopenia have been reported.

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dosage*	Every 12 hours
10-30	Usual Recommended Dosage*	Every 24 hours
<10	Usual Recommended Dosage*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Alternatively, the dosing interval may remain constant at 12 hour intervals, but the dose reduced to one-half the usual recommended dose for patients with a creatinine clearance of 10-30 mL/min, and one-quarter the usual recommended dose for patients with a creatinine clearance of less than 10 mL/min.

When only serum creatinine levels are available, creatinine clearance may be calculated from the following formula. The serum creatinine level should represent a steady state of renal function.

$$\text{Males:} \quad \frac{\text{Weight (kg)} \times (140 - \text{age})}{72 \times \text{serum creatinine (mg/100 mL)}}$$

$$\text{Females:} \quad 0.9 \times \text{value for males}$$

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. CEFOTAN is also available in a pharmacy bulk package of 10 g in 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.

1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21); 10 g in 100 mL vial (NDC 0038-0375-10).

The induction of premature luteolysis in normal women—follicular phase luteinizing hormone secretion and corpus luteum function in the subsequent cycle 989

Michael R. Soules, MD, William J. Bremner, MD, PhD, Kristine D. Dahl, PhD, Jean E. Rivier, PhD, Wylie W. Vale, PhD, and Donald K. Clifton, PhD

Seattle, Washington, and La Jolla, California

Decreased luteal progesterone levels induced by an antagonist to gonadotropin-releasing hormone did not lead to an increased frequency of luteinizing hormone pulses or luteal phase deficiency in the subsequent cycle.

Assessment of current International Federation of Gynecology and Obstetrics staging of vulvar carcinoma relative to prognostic factors for survival (A Gynecologic Oncology Group Study) 997

Howard D. Homesley, MD, Brian N. Bundy, PhD, Alexander Sedlis, MD, Edgardo Yordan, MD, Jonathan S. Berek, MD, Antoine Jahshan, MD, and Rodrique Mortel, MD

Winston-Salem, North Carolina, Buffalo and Brooklyn, New York, Chicago, Illinois, Los Angeles, California, and Philadelphia and Hershey, Pennsylvania

Further refinements are warranted within stage III in the current International Federation of Gynecology and Obstetrics vulvar carcinoma staging system, which is based on analysis of the independent prognostic factors of groin node status and lesion diameter.

Comparison of pulsatile and continuous ritodrine administration: Effects on uterine contractility and the β-adrenergic receptor cascade 1005

Steve N. Caritis, MD, Jye Ping Chiao, MS, and Pam Kridgen, BS

Pittsburgh, Pennsylvania

Administration of identical doses of ritodrine for 24 hours by continuous infusion or by intermittent pulses produces different effects on myometrial β-adrenergic recptors, yet oxytocin-induced contractility is inhibited for 24 hours by both regimens.

Rapid intramembranous absorption into the fetal circulation of arginine vasopressin injected intraamniotically 1013

William M. Gilbert, MD, Cecilia Y. Cheung, PhD, and Robert A. Brace, PhD

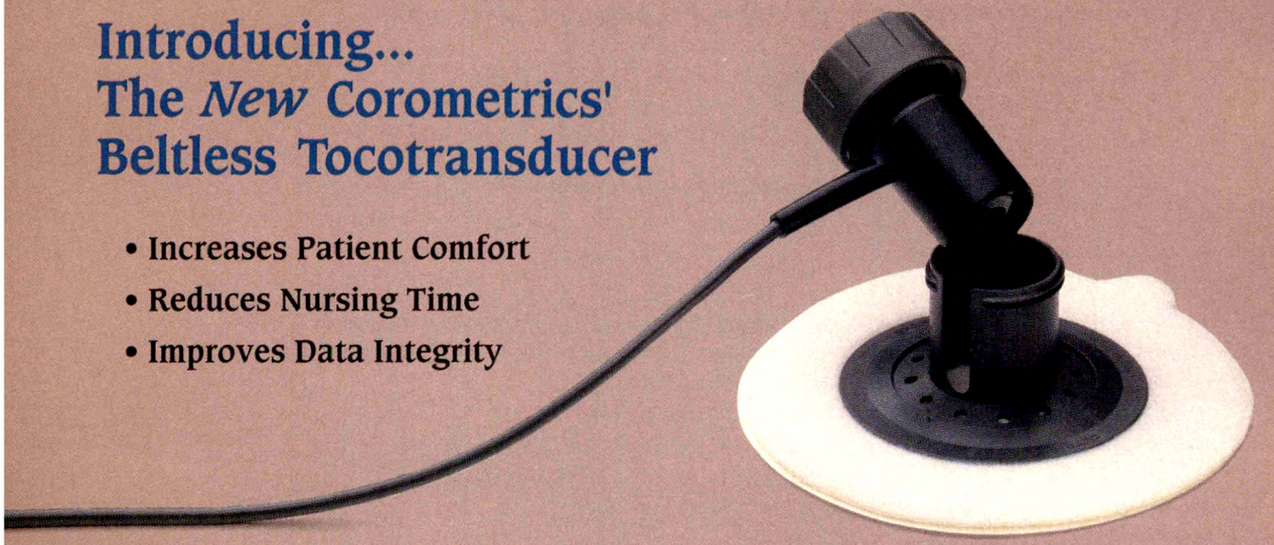
San Diego, California

Intraamniotically injected arginine vasopressin appears rapidly in fetal plasma independent of fetal swallowing, suggesting the intramembranous pathway is primarily involved in the regulation of amniotic fluid volume and composition.

Effect of intravenous cocaine on uterine blood flow in the gravid baboon 1021

Mark A. Morgan, MD, Susan L. Silavin, PhD, Mildred Randolph, DVM, Gerald G. Payne, Jr., MD, Roger E. Sheldon, MD, John I. Fishburne, Jr., MD, Richard A. Wentworth, PhD, and Peter W. Nathanielsz, MD, PhD

Oklahoma City, Oklahoma, and Ithaca, New York



Low-dose intravenous cocaine infusions reduce uterine blood flow in a dose-dependent manner when administered to the unanesthetized, chronically instrumented, pregnant baboon.

Tired of All the Belt Tightening?

Introducing...
The *New* Corometrics' Beltless Tocotransducer

- Increases Patient Comfort
- Reduces Nursing Time
- Improves Data Integrity

Corometrics' unique new Beltless Tocotransducer virtually eliminates instability and inconvenience. A disposable adhesive baseplate holds the transducer securely in place. This system provides reliable, useful readings even during patient position changes, sitting or walking.

Not only do patients enjoy freedom from the constrictive belt, but also nurses appreciate how little attention is required to obtain a clear, continuous reading.

For more information call toll free:
1-800-243-3952, ext. 465.

c-*myc* Protooncogene polypeptide expression in endometriosis 1031
Robert S. Schenken, MD, Julia V. Johnson, MD, and Robert M. Riehl, PhD
San Antonio, Texas

The c-*myc* protooncogene polypeptide was identified in glandular nuclei and cytoplasm and in stromal nuclei of endometriotic tissue obtained during the proliferative phase of the menstrual cycle.

Serum interleukin-6 levels correlate with disease status in patients with epithelial ovarian cancer 1038
Jonathan S. Berek, MD, Catherine Chung, BS, Klara Kaldi, BS, Joanna M. Watson, BSc, Reba M. Knox, MS, and Otoniel Martinez-Maza, PhD
Los Angeles, California

Serum interleukin-6 levels were elevated in the majority of patients with bulky residual epithelial ovarian cancer but not in most patients with microscopic disease.

Ultrasonography in obstetrics and gynecology: The state of the art in 1990 1044

Screening and detection of congenital malformation Roy M. Pitkin, MD *Los Angeles, California* 1045
Ultrasonography is of limited value in screening for congenital malformation.

The current status of maternal and fetal blood flow velocimetry J.A. Low, MD *Kingston, Ontario,Canada* 1049
Doppler assessment of maternal and fetal blood flow velocity should be limited to the investigational setting.

Ultrasonography in the diagnosis of gynecologic disorders J. Robert Willson, MD
Albuquerque, New Mexico 1064
Ultrasonography is a valuable diagnostic aid in women with gynecologic disorders but when used indiscriminantly the information it provides does not justify the cost.

Carrier screening for cystic fibrosis: Implications for obstetric and gynecologic practice 1077
Sherman Elias, MD, George J. Annas, JD, MPH, and Joe Leigh Simpson, MD
Memphis, Tennessee, and Boston, Massachusetts

Although population screening for cystic fibrosis carrier status offers promising results, only individuals or couples with a family history of cystic fibrosis should be offered screening at this time.

Clinical Articles

Determinants of perinatal outcome in pregnancy-induced hypertension with absence of umbilical artery end-diastolic frequencies 1084
Fiona M. Fairlie, MD, Michael Moretti, MD, James J. Walker, MD, and Baha M. Sibai, MD
Glasgow, Scotland, and Memphis, Tennessee

In pregnancy-induced hypertension with absence or reversal of umbilical artery end-diastolic frequencies, the most important determinant of perinatal outcome was gestational age when hypertension occurred.

Intrauterine transfusion treatment of nonimmune hydrops fetalis secondary to human parvovirus B19 infection 1090
Vicken Sahakian, MD, Carl P. Weiner, MD, Stanley J. Naides, MD, Roger A. Williamson, MD, and Laura L. Scharosch, AB
Iowa City, Iowa

Hydrops that is secondary to parvovirus may be treated.

Attitudes on the ethics of abortion, sex selection, and selective pregnancy termination among health care professionals, ethicists, and clergy likely to encounter such situations 1092
Mark I. Evans, MD, Arie Drugan, MD, Sidney F. Bottoms, MD, Lawrence D. Platt, MD, Charles A. Rodeck, MD, Manfred Hansmann, MD, and John C. Fletcher, PhD
Detroit, Michigan, Haifa, Israel, Los Angeles, California, London, England, Bonn, Federal Republic of Germany, and Charlottesville, Virginia

A survey of physicians, ethicists, and clergy likely to encounter multifetal pregnancies suggests variation in acceptability of selective pregnancy termination according to training, religion, and particulars of the pregnancy.

The significance of amniotic fluid volume during intrapartum fetal acoustic stimulation 1100
Albert P. Sarno, Jr., MD, Major, MC, USA
Los Angeles, California, and Honolulu, Hawaii

Amniotic fluid volume appears to play a small role in the genesis of fetal heart rate decelerations after intrapartum fetal acoustic stimulation.

Contents

Successful pregnancy in a patient with Hallermann-Streiff syndrome 1102
Susan L. Hendrix, DO, and Harold J. Sauer, MD
Lansing and East Lansing, Michigan

A 19-year-old woman with a long history of complications from Hallerman-Streiff syndrome and a müllerian anomaly had an uneventful term gestation after artificial insemination.

Fetal vibratory acoustic stimulation in twin gestations with simultaneous fetal heart rate monitoring 1104
David M. Sherer, MD, Jacques S. Abramowicz, MD, Mary Lou D'Amico, RN, Christine B. Caverly, RN, and James R. Woods, Jr., MD
Rochester, New York

Fetal vibratory acoustic stimulation of twin gestations with continuous simultaneous separate recording of each fetal heart rate response is reported.

Fetal death associated with measles virus infection of the placenta 1107
Kazuko Moroi, MD, Siu Saito, MD, Takeshi Kurata, MD, PhD, Tetsutaro Sata, MD, and Masahiko Yanagida, MD
Tokyo, Japan, and Bethesda, Maryland

A case of fetal death at 25 weeks' gestation, which was associated with measles virus infection of the placenta and proved by the immunohistochemical method, is described.

Current Development

Coffee during pregnancy: A reproductive hazard? 1109
Steven A. Narod, MD, Silvia de Sanjosé, MD, PhD, and Cesar Victora, MD, PhD
Lyon, France, and Pelotas, Brazil

Recent studies of possible effects of coffee consumption during pregnancy on birth defects, miscarriages, birth weight, and infertility are reviewed.

BASIC SCIENCE SECTION

A new model for objective assessment of cervical ripening: The effect of prostaglandin E_2 and prelabor contractility 1115
Toru Takahashi, MD, Beth Marcus, BA, Richard G. Scheerer, MD, and Michael Katz, MD
Kawasaki, Japan, and San Francisco, California

The effects of locally applied prostaglandin E_2 and prelabor contractability on cervical ripening in a pregnant rabbit preparation are described.

Evaluation of changes in umbilical blood flow in the fetal lamb by Doppler waveform analysis 1118
Klaus G. Schmidt, MD, Mariarosaria Di Tommaso, MD, Norman H. Silverman, MD, and Abraham M. Rudolph, MD
San Francisco, California

Descending aortic and umbilical artery Doppler waveform analysis in the fetal lamb model failed to detect mild to moderate changes in the umbilical circulation but did indicate severe changes.

Immunohistochemical localization of gonadotropin-releasing hormone during implantation in the New Zealand White rabbit 1127
Paul A. Bergh, MD, Ted L. Anderson, PhD, and Glen E. Hofmann, MD, PhD
New York, New York, and Nashville, Tennessee

Gonadotropin-releasing hormone was immunohistochemically localized weakly to the syncytiotrophoblast and strongly to the cytotrophoblast during implantation in the rabbit.

Passive membrane properties and inward calcium current of human uterine smooth muscle cells 1132
Roger C. Young, MD, PhD, Lea Herndon Smith, and Nels C. Anderson, Jr., PhD
Durham, North Carolina, and Charleston, South Carolina

Quantitative electrophysiologic experiments that characterized action potentials and voltage-activated calcium channels were performed on single human uterine myocytes.

Intraabdominal sound levels during vibroacoustic stimulation 1140
Ernest M. Graham, MD, Aemil J.M. Peters, Robert M. Abrams, PhD, Kenneth J. Gerhardt, PhD, and David J. Burchfield, MD
Gainesville, Florida

Sound pressure levels in the abdomen of sheep vary with applied static force and frequency of vibration on abdominal surface.

Effect of progesterone on renin secretion in endometrial stromal, chorionic trophoblast, and mesenchymal monolayer cultures 1145
Dinesh M. Shah, MD, Kazumi Higuchi, MD, PhD, Tadashi Inagami, PhD, and Kevin G. Osteen, PhD
San Antonio, Texas, and Nashville, Tennessee

Endometrial stromal cells in culture secrete high amounts of active renin compared with mesenchymal cell cultures, and progesterone stimulates further active renin secretion.

IN POSTPARTUM ENDOMETRITIS*

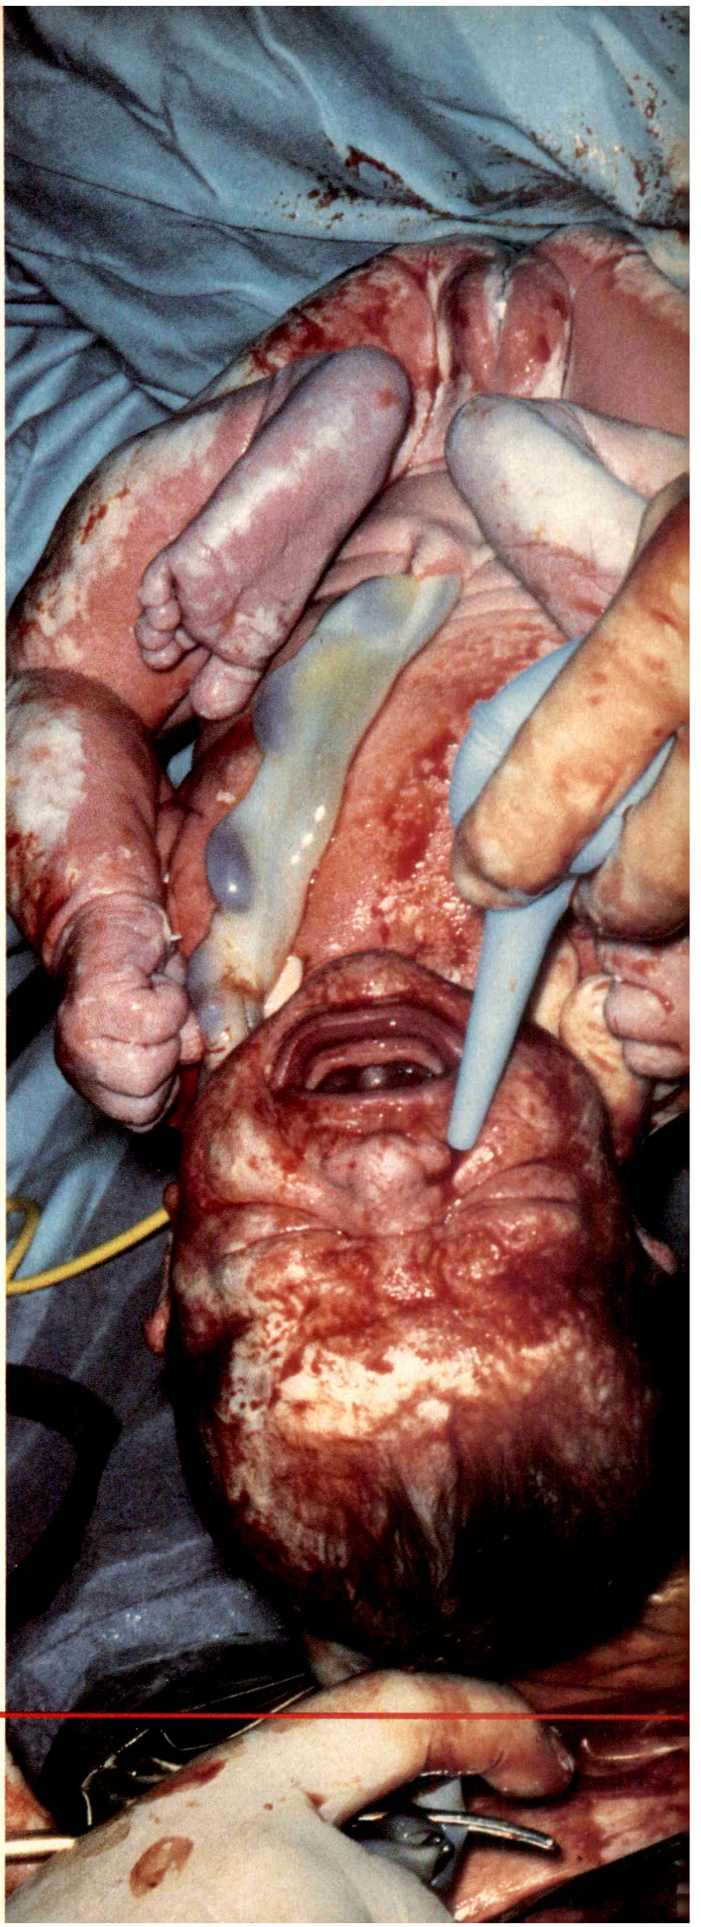
A randomized, comparative trial of AZACTAM versus gentamicin, each with clindamycin, for the treatment of endometritis after delivery.[1]

No universal criteria exist that may satisfy a single definition of "cure." Use of this term may vary between clinical settings and investigators, and the reader is urged to consult the reference listed.

Azactam®
aztreonam
delivers...

*Due to susceptible organisms.

†Although a useful guide, in vitro data do not necessarily correlate with therapeutic outcome.



‡Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. See full prescribing information for recommendations on patients with immediate hypersensitivity reactions to penicillins.

Following IV administration, the most commonly seen adverse reactions occurred in less than 2% of patients, including local reactions, diarrhea, nausea/vomiting, and rash.

more than you're expecting...

- *Broad aerobic gram-negative in vitro coverage, including Escherichia coli, Proteus mirabilis, and Enterobacter cloacae.†*
- *Greater than 90% cure rates in combination with clindamycin.[1-3]*
- *No time-consuming, costly, routine therapeutic drug monitoring.*
- *May be admixed in the same bag with clindamycin.*
- *May be used in penicillin-allergic patients.‡*
- *Pregnancy Category B.*

There are no adequate and well-controlled studies in pregnant women. AZACTAM should be used in pregnant women only if clearly needed.

Azactam®
aztreonam

A logical alternative to aminoglycosides.

Please see adjacent page for brief summary of prescribing information.

Azactam®
aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION–AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE–Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca*, Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis*, Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae*, Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae*, Enterobacter* species* including *E. cloacae*,* and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy–Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organisms(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATIONS–Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS–Pseudomembranous colitis has been reported with nearly all antibacterial agents, including aztreonam, and may range in severity from mild to life-threatening. Therefore, it is important to consider this diagnosis in patients who present with diarrhea subsequent to the administration of antibacterial agents.

Treatment with antibacterial agents alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of "antibiotic-associated colitis."

After the diagnosis of pseudomembranous colitis has been established, therapeutic measures should be initiated. Mild cases of pseudomembranous colitis usually respond to drug discontinuation alone. In moderate to severe cases, consideration should be given to management with fluids and electrolytes, protein supplementation, and treatment with an oral antibacterial drug effective against *C. difficile* (e.g., vancomycin). Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

*Efficacy for this organism in this organ system was studied in fewer than ten infections.

PRECAUTIONS–General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility–Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy–Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers–Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use–Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS–Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity; *Hypersensitivity*–anaphylaxis. *Hematologic*–pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*–abdominal cramps; rare cases of *C. difficile*-associated diarrhea, including pseudomembranous colitis, or gastrointestinal bleeding have been reported. Onset of pseudomembranous colitis symptoms may occur during or after antibiotic treatment (see WARNINGS). *Dermatologic*–purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*–hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*–one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*–hepatitis, jaundice. *Nervous System*–seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*–muscular aches. *Special Senses*–tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*–vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*–weakness, headache, fever, malaise.

Adverse Laboratory Changes–Those reported without regard to drug relationship during clinical trials were: *Hepatic*–elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*–increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*–increases in serum creatinine.

OVERDOSAGE–If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION–Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED–AZACTAM For Injection (Aztreonam For Injection)–Lyophilized–is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam). (J4-231C)

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1988;108:258-65. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL.

Manuscript submission. Manuscripts should be submitted to one of the two Editors in Chief as follows:

1. **Dr. Zuspan**—manuscripts from the eastern United States and from England, Israel, and Italy, manuscripts written for Clinical Opinion and Current Development, Letters to the Editors, and all manuscripts presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation. *Manuscripts from The Society of Perinatal Obstetricians should be submitted to Dr. Donald R. Coustan, Department of Obstetrics and Gynecology, Women and Infants Hospital of Rhode Island, 101 Dudley St., Providence, RI 02905.*
2. **Dr. Quilligan**—manuscripts from states west of Pennsylvania, West Virginia, Kentucky, Tennessee, and Mississippi; manuscripts from Hawaii, Alaska, Canada, and abroad (except England, Israel, and Italy). Dr. Quilligan is responsible for manuscripts from the Society for Gynecologic Investigation. *Manuscripts from the Society for Gynecologic Investigation should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033.*

Author's designation of reviewers. When authors submit their manuscripts, they should provide the names and addresses of at least three reviewers for consideration by the Editors.

Copyright statement. The specified copyright statement that follows the Information for Authors in each issue of the JOURNAL must be completed, signed by all authors, and submitted with the manuscript. (The Checklist and Copyright Statement may be torn from the JOURNAL or photocopied for submission.) If not completed in full, it will be returned to the author for completion.

Checklist. The checklist that appears with the copyright statement in each issue of the JOURNAL must be fully completed by the author(s) and sent with each submitted manuscript. A more complete description of each item that must be checked is provided under the appropriate heading in the Information for Authors, which is published in each issue of the JOURNAL. *If the checklist is not completed in full, the deficiencies will be noted, and the form, as well as the manuscript when necessary, will be returned to the author for completion.*

Previous publication. If a report by the same author(s) has been previously published in any medium that deals in any respect whatever with the same patients, same animals, same laboratory experiments, or same data, in part or in full, as those reported in the manuscript being submitted, two reprints of the article or two copies of the manuscript, be it a full-length report or an abstract, must be submitted with the manuscript. The author(s) should inform the Editor of the circumstances, similarities, and differences of the reports. This requirement also applies to the submission of a manuscript in which a few different patients, animals, laboratory experiments, or data were added to those reported in a previous publication or in a submitted or accepted manuscript. Articles previously published in another language will not be considered.

Human and animal experimentation. It is assumed by the Editors that manuscripts emanating from a particular institution are submitted with the approval of the requisite authority. Human experimentation that requires local institutional approval must have this approval *before the ex-*

periment is started and approval must be so indicated in the Methods section of the submitted manuscript. Reports of experiments on animals must *state in the Methods section of the manuscript* that the guidelines for the care and use of the animals *approved by the local institution* were followed. The species of nonhuman animals used in an investigation must be named in the title, abstract, and key words of the manuscript.

Authorship. For manuscripts with two or more authors, each author must qualify by having participated actively and sufficiently in the study that is being performed and reported. The inclusion of each author in the authorship list of a report is based only (1) on substantial contributions to (a) concept and design, or analysis and interpretation of data and (b) drafting the manuscript or revising it critically for important intellectual content; and (2) on final approval by each author of the version of the manuscript. Conditions 1 (a and b) and 2 must both be met. Others contributing to the work should be recognized separately in an Acknowledgment. In the covering letter that accompanies the submitted manuscript, it must be confirmed that all authors fulfilled both conditions.

Conflict of interest. Authors are expected to inform the Editor, in a letter accompanying the submitted manuscript, of any commercial association that might pose a conflict of interest, such as ownership, stock holdings, equity interests and consultant activities, or patent-licensing situations. Such information is confidential, is not given to the consultants, and does not play a part in the decision of the quality or timeliness of the manuscript. If the manuscript is accepted, the author and the Editor will determine how best to release the information. The usual and customary listing of sources of support and institutional affiliations on the title page is proper and does not imply a conflict of interest; only where there is a possible conflict of interest is the author(s) expected to inform the Editor.

Disclaimer. Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher, and the Editor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality photocopies of the manuscript and three sets of glossy prints of illustrations are required.

Manuscripts must be typed double-spaced on one side only of 22 × 28 cm (8½ × 11 inch) white bond paper with 1-inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, condensation, abstract, body of text, acknowledgments, references, figure legends, and tables.

Title page. The title page (page 1) should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of each author and each author's highest academic degree (both MD and PhD are acceptable, but honors degrees are not permitted); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; source(s) of financial support; presented line, if applicable; disclaimers, if any; name, address, business and home telephone numbers, and fax number of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name, address, business and home telephone numbers, and fax number of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Condensation. On page 2 of the manuscript provide a brief, concise condensation, typed double-spaced, that will appear with the title in publication of the Contents pages of the JOURNAL. It should be a single-spaced sentence, limited to a maximum of 25 words, delineating the essential point(s) made in the manuscript.

Abstract page and key words/phrases. On manuscript page 3, type the abstract, double-spaced, with the required margins and headed by the title of the article and name(s) of author(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations, since the emphasis is on the "action" rather than on the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods* section describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results* section present the detailed findings. Include mentions of all tables and/or figures. Figures and tables should supplement, not duplicate, the text; presentation of data in either one or the other will suffice. Emphasize only your important observations; do not compare

Estimating length of manuscripts

With the exception of Current Development articles, the length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A text of 4200 words or more can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7-page article in the JOURNAL. The 2000 words of text alone makes approximately 8 pages of manuscript typed double-spaced with the required 1-inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 words in manuscript. Thus, if a greater number of illustrations and tables is used, the length of the text should be adjusted accordingly.

your observations with those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment* section state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number (25) is allowed, except in case reports and brief communications (limited to 2) and in manuscripts for the Current Development section (for which there is no limit). Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" (Vancouver style) (Ann Intern Med 1988;108:258-65). Journal titles should conform to abbreviations used in *Cumulated Index Medicus*.

Examples (if six or fewer authors, list all; if seven or more authors, list three then et al.):

JOURNAL: Flamm BL, Dunnett C, Fischermann E, Quilligan EJ. Vaginal delivery following cesarean section: use of oxytocin augmentation and epidural anesthesia with internal tocodynamic and internal fetal monitoring. AM J OBSTET GYNECOL 1984;148:759-63.

BOOKS: Ledger WJ. Dystocia and prolonged labor. In: Wilson JR, Carrington ER, eds. Obstetrics and gynecology. St. Louis: CV Mosby, 1987 vol 8:474-93.

Personal communications and unpublished data, if essential, may be used but not as numbered references. If they are used, they are to be referred to, within parentheses, at the appropriate location in the text. If used, the author(s) must obtain written and signed permission for their use from the individual being quoted. This signed permission must accompany the manuscript when it is submitted to the Editor. Published abstracts can be used as numbered references; however, reference to the complete published article is preferred.

Figures. The term *figure* includes all types of illustrations such as graphs, diagrams, photographs, flow charts, and line drawings. A reasonable number of figures will be reproduced without charge, but special arrangements must be made with the Editors for color figures at an additional charge to the author. The quoted charge is per page of color, and as many as eight color figures can be included on one page.

Figures must be cited consecutively in the text in Arabic numerals and identified with a gummed label on the back of the figure with author(s) name(s), title of article, figure number, and top marked clearly. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Do not use paper clips or mar the surface of figures in any way. Figures will be returned only on request by the author.

For *black-and-white figures,* submit three sets of 3 × 4 inch (minimum) to 5 × 7 inch (maximum) unmounted, glossy prints. All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy prints with good black-and-white contrast.

For *color figures* submit original transparencies and two sets of unmounted prints on glossy (smooth surface) paper. Polaroid prints are not acceptable. Color transparencies must have a color balance (consistency in lighting and film speed) that is acceptable to the author and Editors before acceptance for publication. Please note that 35 mm transparencies are enlarged to twice their original size. If it is important to deviate from this standard, please so indicate when the material is submitted. The top, first author's last name, and figure number must be indicated on the front of each transparency and the back of each print.

Computer-generated figures must be legible and clearly printed in jet black ink on heavy coated paper with either a glossy or dull finish. Any patterns or shadings must be dark enough for reproduction and must be distinguishable from each other. Lines, symbols, and letters should be both smooth and complete. The legend should not appear on the figure. On the back of each figure the name of the first author and the figure number should be given and the top indicated. Three original individual laser or plotter prints are to be submitted *unmounted* with the manuscript. Laser prints should be full size at 300 dots per inch (DPI) or greater full-page resolution; multiple illustrations on a page cannot be accepted. Dot matrix prints and photographic halftones are not acceptable. *Color figures* are acceptable, but special arrangements must be made with the Editors. The colors used must be dark enough and of sufficient contrast for reproduction. With the exception of fluorescent colors, all colors can be reproduced in four-color figures.The preparation and submitting of color prints should fol-

low the preceding guidelines for black-and-white computer-generated illustrations.

Legends to figures. Legends for all figures must be typed double-spaced on paper separate from the text of the manuscript, and these pages must be numbered in sequence after the references. Titles should be included in the legend, not on the print. Original magnifications should be provided. If a figure has been taken from copyrighted material, the legend must give full credit to the original source.

Tables. Tables should be typed on separate sheets of paper, one table to a page, and included at the end of the text. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Titles should be brief yet indicate clearly the purpose or content of each table, and each column should be precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. If a table or any part thereof has been taken from copyrighted material, a footnote to the table must give full credit to the original source. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Permissions. Direct quotations, tables, or figures that have appeared in copyrighted material must be accompanied by written permission for their use from the copyright owner and original author along with complete information as to source. Photographs of identifiable persons must be accompanied by signed releases. If not, all recognizable features must be masked.

Requirements for manuscripts

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for regular article.

Clinical Opinion. Limit of 3000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Letters to the Editors. Letters to the Editors must be submitted in duplicate, typed double-spaced, and the text of the manuscript must be limited to a maximum of 400 words (excluding references, name(s) and address(es) of the signer(s), and the phrase "To the Editors"). The submitted Letter to the Editors must be accompanied by a signed copyright statement. If there are two or more signers of the Letter to the Editors, one of the authors may sign the copyright statement but must add to the statement the following: "I sign for and accept responsibility for releasing this letter on behalf of any and all co-signers." These requirements apply to all types of Letters to the Editors. Letters should be sent to Dr. Zuspan.

Two types of letters will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. If the original author does not respond, a notation indicating "Response declined" will be published. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60 U.S., and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Zuspan. No books will be returned.

Reprints

The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

Business communications

Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, Mosby–Year Book, Inc., 11830 Westline Industrial Drive, St. Louis, MO 63146-3318, or call Journal Advertising Production Manager (314) 872-8370.

CHECKLIST AND COPYRIGHT STATEMENT

Both the checklist and the copyright statement forms **must be completed** and sent with each submitted manuscript. If **not** completed, these forms will be returned to the author for completion.

These items appear in each monthly issue of the JOURNAL. A photocopy may be used. An exposition of the requirements given in the checklist is in the Information for Authors, which is published in each issue of the JOURNAL.

CHECKLIST

General

—The original and two copies of the manuscript are submitted.
—The appropriate signed completed checklist and assignment of copyright signed by **all** authors accompany the manuscript.
—Three sets of unmounted glossy prints for regular figures are submitted, properly numbered and labeled on the back of each print.
—Three sets of original computer-generated figures printed on heavy coated paper with either a glossy or dull finish, unmounted, each one on a page, and properly labeled on the back are submitted. None are dot matrix or photographic prints.
—Human experimentation has been approved by the local institution as stated in the Methods section.
—Guidelines for the care and use of animals approved by the institution have been followed as indicated in the Methods section.
—The covering letter with essential information is with the manuscript.
—All elements of the manuscript are typed double-spaced on bond paper with 1-inch margins at top, bottom, and sides.
—All pages are numbered in the following order: title page, condensation, abstract, body of the text, acknowledgments only of persons who have made substantive contributions to the study, references, legends, and tables.
—Signed, written permission from both the copyright holder and the original author for the use of tables, figures, or quotations previously published and their complete references are enclosed with the manuscript.
—Signed, written permission for the use of quotations of personal communications and unpublished data has been obtained from the person(s) being quoted and is enclosed.

Authorship

—In the covering letter that accompanies the submitted manuscript I/we have confirmed that all authors fulfilled both conditions required for authorship.

Conflict of interest

—In the covering letter that accompanies the submitted manuscript the commercial association of the author or of any co-authors that might pose a conflict of interest is described.

Previous publications

—Enclosed with the submitted manuscript are two reprints each of articles the author or co-authors have previously published or have in manuscript form dealing with same patients, same animals, same laboratory experiment, or same data, in part or in full, as those reported in the submitted manuscript. Further explanation is provided in the covering letter that accompanies the submitted manuscript.
—Similarities and differences are identified.

Reviewers

—Names and addresses of three individuals are enclosed.

Title page

—These elements are given in the following sequence, and are typed double-spaced.
—Title.
—Author(s) name(s) and highest academic degree(s) are shown.
—City(ies), state(s), and country other than U.S. in which the study was conducted are given.
—The name(s) of the institution(s) section(s), division(s), department(s) in which the study was performed is provided and the author(s) institutional affiliation at the time of the study is indicated.
—Acknowledgment of financial support is cited.
—Name, address, business and home telephone numbers, and fax number of author to whom requests for reprints are to be sent are included.
—If reprints will not be available, this has been stated on the title page.
—If the corresponding author is different from the author to whom reprint requests are to be sent, his/her name, address, business and home telephone numbers, and fax number have been added.
—At the bottom of the page, a running head not exceeding 52 characters (including word spaces) has been typed.

Condensation

—On a separate sheet of paper, page 2 of the manuscript, a single sentence limited to 25 words delineating the essential point(s) is typed double-spaced.

Abstract

—The abstract is typed double-spaced with required margins (on page 3) headed by the title and the author(s) name, not exceeding 150 words. For case reports and brief communications the limit of 50 words is not exceeded.
—Three to five key words or short phrases are placed beneath the abstract on page 3.

Tables

—Each table headed by a title and numbered in Roman numerals is typed double-spaced on a separate page.

—Tables are cited in sequence in the text.

Figures

—Each is numbered with an Arabic numeral and cited in numerical sequence in the text.

—Original transparencies of **color photographs** appropriately numbered and identified are submitted along with two sets of unmounted prints on glossy paper, numbered and identified on the back.

References

—Are typed double-spaced.

—Are numbered consecutively in the order they are cited in the text.

—The format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" is used. Examples shown in Information for Authors were followed.

—Personal communications, and unpublished work are not used as numbered references but are mentioned in the text with the written approval of the person being quoted. The signed approval is enclosed.

Modern medicine's answer to normal memory loss.

A lively and authoritative review of the year's best journal literature.

Let's face it. Remembering everything from the hundreds of articles you read is a herculean task. You're bound to forget a few important details. It's normal. It's healthy. But with a subscription to the *Year Book of Obstetrics and Gynecology*, it's also unnecessary.

Each year, the *Year Book of Obstetrics and Gynecology* brings you the most important articles relating to obstetrics and gynecology. The articles, chosen by our distinguished editors, are abstracted into concise one and two page summaries for quick and efficient reading. Nearly every article is accompanied by personal commentary from the editors discussing its significance to your daily practice.

The *Year Book of Obstetrics and Gynecology* — it's the best way to remember what you shouldn't forget.

❑ **Yes! I want an overview of the year's most important journal literature.**

Please send my **30-day FREE examination** copy of the *1991 Year Book of Obstetrics and Gynecology* (22118) by Daniel R. Mishell, Jr. If I decide to keep the book I'll pay $57.95 plus shipping and handling.

When you purchase a Year Book, we'll also send you an automatic notice of future volumes about two months before they publish. This system was designed for your convenience and to take up as little of your time as possible. If you do not want the Year Book, the advance notice makes it easy for you to let us know. And if you elect to receive the new Year Book, you need do nothing. We will send it on publication. No worry. No wasted motion. And, of course, every Year Book is yours to examine *free of charge* for 30 days.

TRI·LEVLEN® Levonorgestrel and ethinyl estradiol tablets–Triphasic regimen

TRI-LEVLEN® 28 TRI-LEVLEN® 21

BRIEF SUMMARY

Tri-Levlen®—6 brown tablets, each containing 0.050 mg of levonorgestrel (d(-)-13 beta-ethyl-17-alpha-ethinyl-17-beta-hydroxygon-4-en-3-one), a totally synthetic progestogen, and 0.030 mg of ethinyl estradiol (19-nor-17α-pregna-1,3,5(10)-trien-20-yne-3, 17-diol); 5 white tablets, each containing 0.075 mg levonorgestrel and 0.040 mg ethinyl estradiol; 10 light-yellow tablets, each containing 0.125 mg levonorgestrel and 0.030 mg ethinyl estradiol (7 light-green tablets containing inert ingredients are included in the 28-day triphasic regimen).

Indications and Usage

Oral contraceptives are indicated for the prevention of pregnancy in women who elect to use this product as a method of contraception.

Contraindications

Oral contraceptives should not be used in women with any of the following conditions: thrombophlebitis or thromboembolic disorders, a past history of deep-vein thrombophlebitis or thromboembolic disorders, cerebral-vascular or coronary-artery disease, known or suspected carcinoma of the breast, carcinoma of the endometrium or other known or suspected estrogen-dependant neoplasia, undiagnosed abnormal genital bleeding, cholestatic jaundice of pregnancy or jaundice with prior pill use, hepatic adenomas or carcinomas, known or suspected pregnancy.

Warnings

Cigarette smoking increases the risk of serious cardiovascular side effects from oral-contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risks of several serious conditions including myocardial infarction, thromboembolism, stroke, hepatic neoplasia, gallbladder disease, and hypertension, although the risk of serious morbidity or mortality is very small in healthy women without underlying risk factors. The risk of morbidity and mortality increases significantly in the presence of other underlying risk factors such as hypertension, hyperlipidemias, obesity and diabetes. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks. The information contained in this package insert is principally based on studies carried out in patients who used oral contraceptives with higher formulations of estrogens and progestogens than those in common use today. The effect of long-term use of the oral contraceptives with lower formulations of both estrogens and progestogens remains to be determined. Throughout this labeling, epidemiological studies reported are of two types: retrospective or case control studies and prospective or cohort studies. Case control studies provide a measure of the relative risk of disease, namely, a ratio of the incidence of a disease among oral-contraceptive users to that among nonusers. The relative risk does not provide information on the actual clinical occurrence of a disease. Cohort studies provide a measure of attributable risk, which is the difference in the incidence of disease between oral-contraceptive users and nonusers. The attributable risk does provide information about the actual occurrence of a disease in the population. For further information, the reader is referred to a text on epidemiological methods.

1. *Thromboembolic Disorders and Other Vascular Problems*

a. *Myocardial Infarction.* An increased risk of myocardial infarction has been attributed to oral-contraceptive use. This risk is primarily in smokers or women with other underlying risk factors for coronary-artery disease such as hypertension, hypercholesterolemia, morbid obesity, and diabetes. The relative risk of heart attack for current oral-contraceptive users has been estimated to be two to six. The risk is very low under the age of 30. Smoking in combination with oral-contraceptive use has been shown to contribute substantially to the incidence of myocardial infarctions in women in their mid-thirties or older with smoking accounting for the majority of excess cases. Mortality rates associated with circulatory disease have been shown to increase substantially in smokers over the age of 35 and non-smokers over the age of 40 among women who use oral contraceptives. Oral contraceptives may compound the effects of well-known risk factors, such as hypertension, diabetes, hyperlipidemias, age and obesity. In particular, some progestogens are known to decrease HDL cholesterol and cause glucose intolerance, while estrogens may create a state of hyperinsulinism. Oral contraceptives have been shown to increase blood pressure among users (see section 9 in "Warnings"). Similar effects on risk factors have been associated with an increased risk of heart disease. Oral contraceptives must be used with caution in women with cardiovascular disease risk factors.

b. *Thromboembolism.* An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Case control studies have found the relative risk of users compared to nonusers to be 3 for the first episode of superficial venous thrombosis, 4 to 11 for deep-vein thrombosis or pulmonary embolism, and 1.5 to 6 for women with predisposing conditions for venous thromboembolic disease. Cohort studies have shown the relative risk to be somewhat lower, about 3 for new cases and about 4.5 for new cases requiring hospitalization. The risk of thromboembolic disease due to oral contraceptives is not related to length of use and disappears after pill use is stopped. A two-to four-fold increase in relative risk of postoperative thromboembolic complications has been reported with the use of oral contraceptives. The relative risk of venous thrombosis in women who have predisposing conditions is twice that of women without such medical conditions. If feasible, oral contraceptives should be discontinued at least four weeks prior to and for two weeks after elective surgery of a type associated with an increase in risk of thromboembolism and during and following prolonged immobilization. Since the immediate post partum period is also associated with an increased risk of thromboembolism, oral contraceptives should be started no earlier than four to six weeks after delivery in women who elect not to breast-feed, or a midtrimester pregnancy termination.

c. *Cerebrovascular diseases.* Oral contraceptives have been shown to increase both the relative and attributable risks of cerebrovascular events (thrombotic and hemorrhagic strokes), although, in general, the risk is greatest among older (>35 years), hypertensive women who also smoke. Hypertension was found to be a risk factor for both users and nonusers, for both types of strokes, while smoking interacted to increase the risk for hemorrhagic strokes. In a large study, the relative risk of thrombotic strokes has been shown to range from 3 for normotensive users to 14 for users with severe hypertension. The relative risk of hemorrhagic stroke is reported to be 1.2 for nonsmokers who used oral contraceptives, 2.6 for smokers who did not use oral contraceptives, 7.6 for smokers who used oral contraceptives, 1.8 for normotensive users and 25.7 for users with severe hypertension. The attributable risk is also greater in older women.

d. *Dose-related risk of vascular disease from oral contraceptives.* A positive association has been observed between the amount of estrogen and progestogen in oral contraceptives and the risk of vascular disease. A decline in serum high-density lipoproteins (HDL) has been reported with many progestational agents. A decline in serum high-density lipoproteins has been associated with an increased incidence of ischemic heart disease. Because estrogens increase HDL cholesterol, the net effect of an oral contraceptive depends on a balance achieved between doses of estrogen and progestogen and the nature and absolute amount of progestogen used in the contraceptive. The amount of both hormones should be considered in the choice of an oral contraceptive. Minimizing exposure to estrogen and progestogen is in keeping with good principles of therapeutics. For any particular estrogen/progestogen combination, the dosage regimen prescribed should be one which contains the least amount of estrogen and progestogen that is compatible with a low failure rate and the needs of the individual patient. New acceptors of oral-contraceptive agents should be started on preparations containing less than 50 mcg of estrogen.

e. *Persistence of risk of vascular disease.* There are two studies which have shown persistence of risk of vascular disease for ever-users of oral contraceptives. In a study in the United States, the risk of developing myocardial infarction after discontinuing oral contraceptives persists for at least 9 years for women 40-49 years who had used oral contraceptives for five or more years, but this increased risk was not demonstrated in other age groups. In another study in Great Britain, the risk of developing cerebrovascular disease persisted for at least 6 years after discontinuation of oral contraceptives, although excess risk was very small. However, both studies were performed with oral-contraceptive formulations containing 50 micrograms or higher of estrogens.

2. *Estimates of Mortality from Contraceptive Use.* One study gathered data from a variety of sources which have estimated the mortality rate associated with different methods of contraception at different ages. These estimates include the combined risk of death associated with contraceptive methods plus the risk attributable to pregnancy in the event of method failure. Each method of contraception has its specific benefits and risks. The study concluded that with the exception of oral-contraceptive users 35 and older who smoke and 40 and older who do not smoke, mortality associated with all methods of birth control is less than that associated with childbirth. The observation of a possible increase in risk of mortality with age for oral-contraceptive users is based on data gathered in the 1970's–but not reported until 1983. However, current clinical practice involves the use of lower estrogen dose formulations combined with careful restriction of oral-contraceptive use to women who do not have the various risk factors listed in this labeling. Because of these changes in practice and, also, because of some limited new data which suggest that the risk of cardiovascular disease with the use of oral contraceptives may now be less than previously observed, the Fertility and Maternal Health Drugs Advisory Committee was asked to review the topic in 1989. The Committee concluded that although cardiovascular-disease risks may be increased with oral-contraceptive use after age 40 in healthy nonsmoking women (even with the newer low-dose formulations), there are greater potential health risks associated with pregnancy in older women and with the alternative surgical and medical procedures which may be necessary if such women do not have access to effective and acceptable means of contraception. Therefore, the Committee recommended that the benefits of oral-contraceptive use by healthy nonsmoking women over 40 may outweigh the possible risks. Of course, older women, as all women who take oral contraceptives, should take the lowest possible dose formulation that is effective.

3. *Carcinoma of the Reproductive Organs.* Numerous epidemiological studies have been performed on the incidence of breast, endometrial, ovarian and cervical cancer in women using oral contraceptives. The overwhelming evidence in the literature suggests that use of oral contraceptives is not associated with an increase in the risk of developing breast cancer, regardless of the age and parity of first use or with most of the marketed brands and doses. The Cancer and Steroid Hormone (CASH) study also showed no latent effect on the risk of breast cancer for at least a decade following long-term use. A few studies have shown a slightly increased relative risk of developing breast cancer, although the methodology of these studies, which included differences in examination of users and nonusers and differences in age at start of use, has been questioned. Some studies suggest that oral-contraceptive use has been associated with an increase in the risk of cervical intraepithelial neoplasia in some populations of women. However, there continues to be controversy about the extent to which such findings may be due to differences in sexual behavior and other factors. In spite of many studies of the relationship between oral-contraceptive use and breast and cervical cancers, a cause-and-effect relationship has not been established.

4. *Hepatic Neoplasia.* Benign hepatic adenomas are associated with oral-contraceptive use, although the incidence of benign tumors is rare in the United States. Indirect calculations have estimated the attributable risk to be in the range of 3.3 cases/100,000 for users, a risk that increases after four or more years of use. Rupture of rare, benign, hepatic adenomas may cause death through intra-abdominal hemorrhage. Studies from Britain have shown an increased risk of developing hepatocellular carcinoma in long-term (>8 years) oral-contraceptive users. However, these cancers are extremely rare in the U.S. and the attributable risk (the excess incidence) of liver cancers in oral-contraceptive users approaches less than one per million users.

5. *Ocular Lesions.* There have been clinical case reports of retinal thrombosis associated with the use of oral contraceptives. Oral contraceptives should be discontinued if there is unexplained partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions. Appropriate diagnostic and therapeutic measures should be undertaken immediately.

6. *Oral-Contraceptive Use Before or During Early Pregnancy.* Extensive epidemiological studies have revealed no increased risk of birth defects in women who have used oral contraceptives prior to pregnancy. Studies also do not suggest a teratogenic effect, particularly insofar as cardiac anomalies and limb-reduction defects are concerned, when taken inadvertently during early pregnancy. The administration of oral contraceptives to induce withdrawal bleeding should not be used as a test for pregnancy. Oral contraceptives should not be used during pregnancy to treat threatened or habitual abortion. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing oral-contraceptive use. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period. Oral-contraceptive use should be discontinued if pregnancy is confirmed.

7. *Gallbladder Disease.* Earlier studies have reported an increased lifetime relative risk of gallbladder surgery in users of oral contraceptives and estrogens. More recent studies, however, have shown that the relative risk of developing gallbladder disease among oral-contraceptive users may be minimal. The recent findings of minimal risk may be related to the use of oral-contraceptive formulations containing lower hormonal doses of estrogens and progestogens.

8. *Carbohydrate and Lipid Metabolic Effects.* Oral contraceptives have been shown to cause glucose intolerance in a significant percentage of users. Oral contraceptives containing greater than 75 micrograms of estrogens cause hyperinsulinism, while lower doses of estrogen cause less glucose intolerance. Progestogens increase insulin secretion and create insulin resistance, this effect varying with different progestational agents. However, in the nondiabetic woman, oral contraceptives appear to have no effect on fasting blood glucose. Because of these demonstrated effects, prediabetic and diabetic women should be carefully observed while taking oral contraceptives. A small proportion of women will have persistent hypertriglyceridemia while on the pill. As discussed earlier (see "Warnings" 1a. and 1d.), changes in serum triglycerides and lipoprotein levels have been reported in oral-contraceptive users.

9. *Elevated Blood Pressure.* An increase in blood pressure has been reported in women taking oral contraceptives and this increase is more likely in older oral-contraceptive users and with continued use. Data from the Royal College of General Practitioners and subsequent randomized trials have shown that the incidence of hypertension increases with increasing quantities of progestogens. Women with a history of hypertension or hypertension-related diseases, or renal disease should be encouraged to use another method of contraception. If women with hypertension elect to use oral contraceptives, they should be monitored closely, and if significant elevation of blood pressure occurs, oral contraceptives should be discontinued. For most women, elevated blood pressure will return to normal after stopping oral contraceptives, and there is no difference in the occurrence of hypertension among ever-and never-users.

10. *Headache.* The onset or exacerbation of migraine or development of headache with a new pattern that is recurrent, persistent or severe requires discontinuation of oral contraceptives and evaluation of the cause.

11. *Bleeding Irregularities.* Breakthrough bleeding and spotting are sometimes encountered in patients on oral contraceptives, especially during the first three months of use. The type and dose of progestogen may be important. Nonhormonal causes should be considered and adequate diagnostic measures taken to rule out malignancy or pregnancy in the event of breakthrough bleeding, as in the case of any abnormal vaginal bleeding. If pathology has been excluded, time or a change to another formulation may solve the problem. In the event of amenorrhea, pregnancy should be ruled out. Some women may encounter post-pill amenorrhea or oligomenorrhea, especially when such a condition was preexistent.

Precautions

1. PHYSICAL EXAMINATION AND FOLLOW UP. A complete medical history and physical examination should be taken prior to the initiation or reinstitution of oral contraceptives and at least annually during use of oral contraceptives. These physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including cervical cytology, and relevant laboratory tests. In case of undiagnosed, persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be conducted to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules should be monitored with particular care. 2. LIPID DISORDERS. Women who are being treated for hyperlipidemias should be followed closely if they elect to use oral contraceptives. Some progestogens may elevate LDL levels and may render the control of hyperlipidemias more difficult. (See "Warnings" 1d.) 3. LIVER FUNCTION. If jaundice develops in any woman receiving such drugs, the medication should be discontinued. Steroid hormones may be poorly metabolized in patients with impaired liver function. 4. FLUID RETENTION. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention. 5. EMOTIONAL DISORDERS. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug related. Women with a history of depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. 6. CONTACT LENSES. Contact-lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist. 7. DRUG INTERACTIONS. Reduced efficacy and increased incidence of breakthrough bleeding and menstrual irregularities have been associated with concomitant use of rifampin. A similar association, though less marked, has been suggested with barbiturates, phenylbutazone, phenytoin sodium, and possibly with griseofulvin, ampicillin and tetracyclines. 8. INTERACTIONS WITH LABORATORY TESTS. Certain endocrine-and liver-function tests and blood components may be affected by oral contraceptives: a. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. b. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column or by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. c. Other binding proteins may be elevated in serum. d. Sex-binding globulins are increased and result in elevated levels of total circulating sex steroids and corticoids; however, free or biologically active levels remain unchanged. e. Triglycerides may be increased. f. Glucose tolerance may be decreased. g. Serum folate levels may be depressed by oral-contraceptive therapy. This may be of clinical significance if a woman becomes pregnant shortly after discontinuing oral contraceptives. 9. CARCINOGENESIS. See "Warnings" section. 10. PREGNANCY. Pregnancy Category X. See "Contraindications" and "Warnings" sections. 11. NURSING MOTHERS. Small amounts of oral-contraceptive steroids have been identified in the milk of nursing mothers and a few adverse effects on the child have been reported, including jaundice and breast enlargement. In addition, oral contraceptives given in the postpartum period may interfere with lactation by decreasing the quantity and quality of breast milk. If possible, the nursing mother should be advised not to use oral contraceptives but to use other forms of contraception until she has completely weaned her child.

Information for the Patient

See Patient Labeling.

Adverse Reactions

An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see "Warnings" section): thrombophlebitis, arterial thromboembolism, pulmonary embolism, myocardial infarction, cerebral hemorrhage, cerebral thrombosis, hypertension, gallbladder disease, hepatic adenomas or benign liver tumors.

There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: mesenteric thrombosis, retinal thrombosis.

The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug related: nausea; vomiting; gastrointestinal symptoms (such as abdominal cramps and bloating); breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; temporary infertility after discontinuation of treatment; edema; melasma which may persist; breast changes: tenderness, enlargement, secretion; change in weight (increase or decrease); change in cervical erosion and secretion; diminution in lactation when given immediately postpartum; cholestatic jaundice; migraine; rash (allergic); mental depression; reduced tolerance to carbohydrates; vaginal candidiasis; change in corneal curvature (steepening); intolerance to contact lenses.

The following adverse reactions have been reported in users of oral contraceptives and the association has been neither confirmed nor refuted: congenital anomalies, premenstrual syndrome, cataracts, optic neuritis, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of scalp hair, erythema multiforme, cerebral-vascular disease with mitral valve prolapse, lupus-like syndromes, erythema nodosum, hemorrhagic eruption, vaginitis, porphyria, impaired renal function, hemolytic uremic syndrome, Budd-Chiari syndrome, acne, changes in libido, colitis, sickle-cell disease.

Overdosage

Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Noncontraceptive Health Benefits

The following noncontraceptive health benefits related to the use of oral contraceptives are supported by epidemiological studies which largely utilized oral-contraceptive formulations containing doses exceeding 0.035 mg of ethinyl estradiol or 0.05 mg of mestranol.

Effects on menses: increased menstrual cycle regularity, decreased blood loss and decreased incidence of iron-deficiency anemia, decreased incidence of dysmenorrhea.

Effects related to inhibition of ovulation: decreased incidence of functional ovarian cysts, decreased incidence of ectopic pregnancies.

Effects from long-term use: decreased incidence of fibroadenomas and fibrocystic disease of the breast, decreased incidence of acute pelvic inflammatory disease, decreased incidence of endometrial cancer, decreased incidence of ovarian cancer.

Dosage and Administration

To achieve maximum contraceptive effectiveness, TRI-LEVLEN® tablets (Levonorgestrel and Ethinyl Estradiol Tablets—Triphasic Regimen) must be taken exactly as directed and at intervals not exceeding 24 hours.

For full details on dosage and administration see prescribing information in package insert. 60627-0 5/90

TRANSACTIONS OF THE NINTH ANNUAL MEETING OF THE AMERICAN GYNECOLOGICAL AND OBSTETRICAL SOCIETY

Cell adhesion molecules and the regulation of development

Bruce A. Cunningham, PhD

New York, New York

Cell adhesion molecules, in conjunction with the other morphoregulatory molecules, substrate adhesion molecules and cell junctional molecules, are dynamically expressed in coordinate patterns throughout development. Their activities are linked to a variety of cellular processes, and their ability to influence mechanochemical processes allows them to influence a variety of other fundamental developmental events. The clinical significance of these molecules remains to be determined, but they are clearly involved in a number of pathologic conditions and could become the focus of a wide range of diagnostic techniques and eventually even therapeutic designs. (AM J OBSTET GYNECOL 1991;164:939-48.)

Key words: Structural families, expression pattern, perturbation studies, cellular transfection, cancer and other diseases

Over the past decade a variety of new techniques has opened previously inaccessible arenas to molecular and cellular analyses. Among these arenas are the fundamental processes in embryonic development, including cell adhesion and migration. The importance of cell-cell interactions to developmental events has long been noted,[1, 2] but the recent identification and characterization of glycoproteins that mediate such interactions have dramatically altered earlier speculations about the nature of cell adhesion molecules and their role in embryogenesis.[3-5] These glycoproteins not only mediate interactions between cells but are dynamically expressed at critical times and places where they can act as key regulators of developmental events. Because they can affect cell patterns and tissue signaling through mechanochemical effects on cell linkage, shape, and movement, they have been termed morphoregulatory molecules.[6]

Morphoregulatory molecules (Fig. 1) include not only cell adhesion molecules (Fig. 1, *A*) but also substrate adhesion molecules and their receptors (e.g., integrins) and cell junctional molecules. A review of substrate adhesion molecules and cell junctional molecules is beyond the scope of this discussion, but some mention should be made of their relationship to cell adhesion molecules.

Substrate adhesion molecules (Fig. 1, *B*) are a diverse group of extracellular molecules that include collagens, glycoproteins, and proteoglycans.[7-9] They differ from the other morphoregulatory molecules in that they are not necessarily made by the cells that bind them. Substrate adhesion molecules can bind to cells through a number of different kinds of receptors; they can also bind to each other and can influence each others' activities. Some, such as cytotactin-tenascin,[10, 11] can influence cells in unusual ways. For example, neural crest cells will not migrate on cytotactin substrates,[12, 13] and when fibroblasts bind to cytotactin-coated substrates, they will not flatten but will remain round.[14] Such negative activities are probably critical to the mechanisms and timing of a number of developmental processes. The ability of cells to migrate on substrate adhesion molecules appears to be inversely related to their ability to interact with each other in that cell adhesion molecules are down regulated on migrating cells.[15, 16] It is becoming increasingly clear, however, that some cell adhesion molecules are found in excreted or soluble forms that may act as substrate adhesion molecules.[17, 18].

6/6/27339

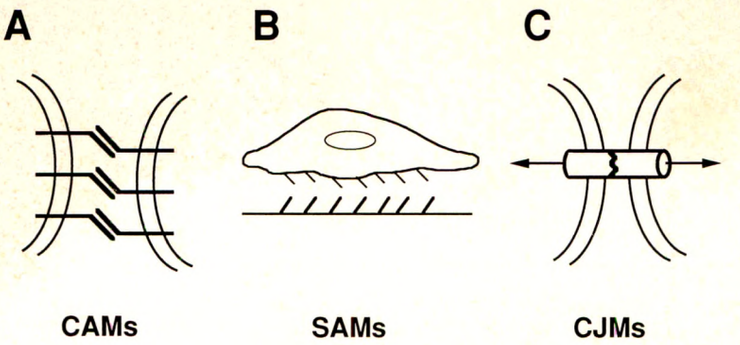

Fig. 1. Morphoregulatory molecules[6] can affect cell patterning events and tissue signaling via mechanical-chemical effects on cell-cell interactions, cell movement, and cell shape.[3] **A**, Cell adhesion molecules *(CAMs bent lines)* are firmly attached to cell surface *(arced double line)* and link cells specifically to each other. **B**, Substrate adhesion molecules *(SAMs, thick, upward-slanted lines)* are found in extracellular matrix *(horizontal line)* and bind to cells via specific receptors *(downward-slanted lines)* on cell surface. **C**, Cell junctions are usually complex structures that include cell junctional molecules *(CJMs)*. Junctions can provide tight seals (tight junctions), communicating links between cells (gap junctions), or attachments to filamentous structure within the cell (adherens junctions and desmosomes).

Cell junctions (Fig. 1, *C*) are relatively elaborate connections between cells that can involve many molecules.[19] They provide seals between cells, allow cells to communicate by transfer of small molecules, and link the cell surfaces with filamentous structures within the cell. The formation of junctions appears to require a prior cell adhesion molecule–mediated event,[20] and some junctions contain cell adhesion molecules or molecules that resemble cell adhesion molecules. For example, adherens junctions can include at least two cell adhesion molecules, A-CAM (adherens junction–specific cell adhesion molecule) (N-cadherin)[21] and L-CAM (uvomorulin),[22] and desmosomes[23] include proteins that are homologous to these calcium-dependent cell adhesion molecules.

Cell adhesion molecules

Cell adhesion molecules (Fig. 1, *A*) are cell surface glycoproteins that either extend through the cell membrane or are attached to the membrane by a lipid anchor. Contrary to earlier notions, there appear to be relatively few kinds of cell adhesion molecules, and a specific molecule can be expressed at a variety of times and places throughout development. This means that when and where a cell adhesion molecule is expressed are as crucial to developmental events as its binding specificity. In addition, specific cell adhesion molecules that are expressed on early embryonic cells are also expressed in a variety of adult tissues. This observation altered previous notions that specific recognition molecules might be expressed only for short periods during development; it also meant that cell adhesion molecules could be isolated from late embryonic or even adult tissues and used for direct biochemical and functional studies.

Different cell adhesion molecules differ in the times at which they are expressed and in the levels of their expression. They can be loosely classified as primary or secondary.[24] Primary cell adhesion molecules such as the neural molecule (N-CAM) and the liver molecule (L-CAM) appear on the earliest embryonic cells and on derivatives of all three germ layers.[15, 16, 25] N-CAM, for example, is seen at least transiently in muscle, heart, liver, kidney, pancreas, lung, and intestine, whereas L-CAM is seen on nearly all epithelia. Secondary cell adhesion molecules such as the neuron-glia molecule (Ng-CAM)[26] appear late in development (after neurulation) and have a highly restricted distribution (postmitotic neurons and Schwann cells). It was anticipated that there would be many more secondary than primary cell adhesion molecules[24] and this notion is gradually being substantiated. N-CAM[27] and L-CAM[28] bind cells by a homophilic mechanism, i.e., a cell adhesion molecule on one cell binds the same one on another. Ng-CAM binds neurons to each other by a homophilic mechanism and neurons to glia by a heterophilic mechanism.[29]

Analyses of their structures have indicated that most cell adhesion molecules can be sorted into one of two families (Fig. 2). Members of one of these families (Fig. 2, *A*) have structural features like those found in antibodies (immunoglobulins) and most closely resemble N-CAM.[30] Ng-CAM, for example, is a member of this family.[31] Members of the other group (Fig. 2, *B*) are more closely related molecules that require calcium for their activity; these calcium-dependent cell adhesion molecules, or cadherins,[4] all resemble L-CAM.[32] The structural similarities among cell adhesion molecules in these two families are greatly aiding efforts to correlate their structure with their functions and in

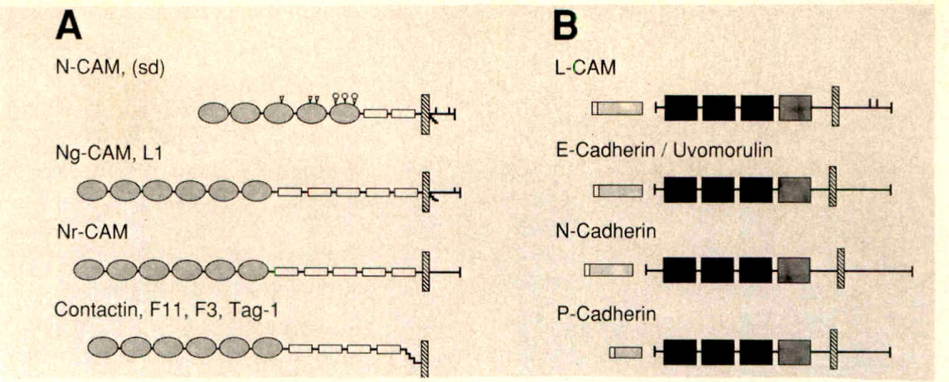

Fig. 2. Structural features of two families of cell adhesion molecules. **A**, All members of the N-CAM family contain immunoglobulin-like domains *(ovals)* and some contain segments resembling fibronectin type III repeats *(rectangles)*. Cell adhesion molecules can extend across the cell membrane *(vertical hatched rectangle)* or attach to the membrane via a lipid linker *(stairstep symbol)*. Included on the model of the most widely distributed form (small cytoplasmic domain, *sd*) of N-CAM[30] are indications of posttranslational modifications: *inverted triangles*, N-linked carbohydrates; *small circles*, polysialic acid, which is unique to N-CAM; and *vertical lines*, sites of phosphorylation on serine or thyronine. The related neural cell adhesion molecules shown are chicken Ng-CAM,[31] mouse L1,[134] chicken Nr-CAM,[135] chicken contactin/F11,[136, 137] mouse F3,[138] and rat TAG-1.[18] **B,** Members of L-CAM family are closely related molecules that require calcium for their activity. They are each made as a larger precursor with a signal sequence *(small open box)* and about 100 amino acids *(thin stippled rectangle)* that are cleaved off before expression on the cell surface. They contain internal segments that are similar to each other *(shaded boxes)*; those shown are all transmembrane *(vertical stippled rectangle)* proteins. Despite their similarities, they have different specificities and tissue distributions; L-CAM[32] and its mammalian equivalent E-cadherin[67] or uvomorulin[66] are found in early embryos and epithelia, whereas N-cadherin[71] is found in brain, lens, and heart and P-cadherin[72] is detected in placenta and endodermal tissues.

some cases[33] have led to the demonstration that molecules having such structures, but having no previously known function (e.g., carcinoembryonic antigen), can act as cell adhesion molecules.

Neural cell adhesion molecule. N-CAM was the first cell adhesion molecule to be isolated[34, 35] and characterized.[30] It has a number of unusual features, including long chains of covalently attached α2,8-linked polysialic acid.[36, 37] This negatively charged sugar is present in largest amounts (30 gm/100 gm protein) in N-CAM from embryonic tissues and decreases to 30% of that value in most adult tissues. The sugar is not directly involved in binding[38] but influences binding so that embryonic forms of N-CAM bind at slower rates than adult forms.[27]

N-CAM (Fig. 2, *A*) has a large extracellular domain that includes five continuous segments that resemble each other and the domains of immunoglobulins that are followed by two segments resembling the type III repeats in fibronectin.[30, 39] The binding region is apparently within the first four immunoglobulin-like domains,[38] whereas the fifth contains the polysialic acid.[40] There are multiple forms of the molecule that differ in the size of their cytoplasmic domains or in the mode of attachment to the membrane.[41, 42] The most widely distributed small cytoplasmic domain form is shown in Fig. 2, *A*. The larger, or large cytoplasmic domain form has a cytoplasmic domain that contains 261 more amino acids than the small cytoplasmic domain form. The third basic form, small surface domain, has no cytoplasmic domain but is attached to the membrane through a phosphatidylinositol linker. Soluble forms of N-CAM are also seen,[43, 44] and there are other variants with small inserts between the fibronectin repeats[17, 44-46] or in the fourth immunoglobulin domain.[47, 48]

All forms of N-CAM appear to undergo the embryonic to adult transition in the sialic acid component, and the individual forms are differently expressed. The large cytoplasmic domain form is seen only in neural tissues,[49, 50] whereas the small surface domain form is seen in muscle, glia, and other specialized locations.[41, 43, 46] The small cytoplasmic domain form is seen in varying amounts in nearly all tissues where N-CAM is expressed.

All forms of N-CAM are derived from a single gene through differential ribonucleic acid splicing.[48, 49] The gene in chickens is large (>70 kb) and has more than 20 exons.[51] The gene has been mapped to mouse chromosome 9[52] and human chromosome 11[53] near a region where a number of translocations are seen.

N-CAM family. Since the description of the structure of N-CAM, a number of cell surface proteins have been described that have many features in common with

CENTRAL LIBRARY

each other and with N-CAM. Some of those found in the nervous system are compared with N-CAM in Fig. 2, *A*. The distinguishing feature is the presence of one or more Ig-like domains that resemble those in N-CAM more closely than those in other immunoglobulin-related molecules (e.g., immunoglobulins, transplantation antigens, β_2-microglobulin). A number of neural cell adhesion molecules belong to this family and most of these also have multiple fibronectin repeats. Other members of the family include those from the immune system,[54, 55] PE-CAM (endo-CAM) found on endothelial cells,[56] and the opioid binding protein OB-CAM.[57] In addition, some members of the N-CAM family are viral receptors,[58] including the poliovirus receptor, CD4 (the human immunodeficiency virus receptor), and I-CAM1 (the rhinovirus receptor).

The resemblance of N-CAM to immunoglobulins, the transplantation antigens, and other members of the immunoglobulin superfamily prompted the suggestion that the evolutionary precursor of N-CAM gave rise to the immune system.[59] Convincing support for this hypothesis has come from the identification of N-CAM-like molecules in the nervous systems of insects,[60-62] which have no adaptive immune system.

L-CAM and related molecules. L-CAM was first detected in chicken liver.[63, 64] Comparable molecules were also found in mammals, including humans,[65] and were given various names; the most commonly used names for these are uvomorulin[66] and E-cadherin.[67] All are assumed to be the same molecule in different species, so here, for simplicity, I generally refer to all of these as L-CAM. L-CAM[32] is a large transmembrane glycoprotein with apparent internal repeats (Fig. 2, *B*), but it does not resemble immunoglobulins, N-CAM, or fibronectin; it has no polysialic acid and is expressed in only a single form. It binds calcium and requires calcium for its homophilic binding activity and biochemical integrity.

The gene for L-CAM[68] is small (10 kb) and complex (>16 exons), but there is no evidence for differential splicing. In mice it is located on chromosome 8[69] and in humans on chromosome 16.[70]

A variety of other calcium-dependent cell adhesion molecules, or cadherins, have been described.[4] They include N-cadherin[71] or A-CAM[21] found in the nervous system, heart, and lens; P-cadherin,[72] found in placenta and endodermal cells; and more recently T-cadherin,[73] from the nervous system, and V-cadherin,[74] from endothelial cells. L-CAM, P-cadherin, and N-cadherin (Fig. 2, *B*) are 50% to 80% identical in amino acid sequence but have different binding specificities and different tissue distributions; the gene for N-cadherin is on a different human chromosome (chromosome 18) than that for L-CAM.[75]

Expression of cell adhesion molecules

An outstanding feature of cell adhesion molecules is their dynamic pattern of expression at critical sites throughout development. These observations alone are sufficient to indicate their active role in development. Some primary cell adhesion molecules are detected either in oocytes or as early as the two-cell stage.[76, 77] On mouse blastocysts L-CAM (uvomorulin) is essential for compaction,[78] and N-CAM and L-CAM are expressed on all cells at early stages, at least in frog and chicken embryos.[15, 16, 25, 77] When cells migrate through the primitive streak to form middle layers or mesoderm, N-CAM is down regulated but is often expressed when mesenchymal cells condense to form epithelia. Later, N-CAM (but not L-CAM) is seen on cells of the neural plate and L-CAM is expressed by itself or together with N-CAM in epithelia that will give rise to skin (ectoderm) or gut (endoderm).

In the early mouse embryo[79, 80] L-CAM (uvomorulin, E-cadherin) is on both embryonic and extraembryonic epithelia. It is on all blastocysts at the lateral border of the trophectoderm but is absent from cell surfaces that contact the zona pellucida. In vitro it is expressed strongly on the inner cell mass and is gradually lost from trophoblastic cells. It is not expressed on the yolk sac or giant trophoblast cells. In vivo it is on embryonic and extraembryonic ectoderm, visceral endoderm chorion, the amniotic fold, and ectoplacental cone but is not seen on mesoderm or germ cells. P-Cadherin is found in the uterine decidua cells and later in the placenta. It is also expressed in the ectoplacental cone, and is has been suggested[79] that P-cadherin may link the embryo to the placenta. Its distribution in human placenta, however, is less clear. Human placenta has been examined only after 6 weeks' gestation,[81] but at this time it expressed higher levels of L-CAM than of P-cadherin.

Interactions between epithelia and mesenchymes that result in embryonic induction[82] lead to expression of genes for the morphoregulatory molecules in addition to those for tissue-specific and cell-specific molecules. Early epithelia express both N-CAM and L-CAM, but subsequently one or the other is lost in patterns that have allowed formulation of a set of place-dependent rules.[25] Other cell adhesion molecules such as N-cadherin and P-cadherin also follow place-dependent expression.[79, 83] In some tissues (e.g., the kidney or the feather) primary cell adhesion molecules can be up regulated and down regulated in cycles at different stages of histogenesis, and then secondary cell adhesion molecules appear at specific sites.

Examples of N-CAM expression[25] in different locations are shown in Fig. 3. In the developing eye (Fig. 3, *A*) it is seen in retina, cornea, and lens. When lens fibers form, N-CAM is not seen in lens but remains in

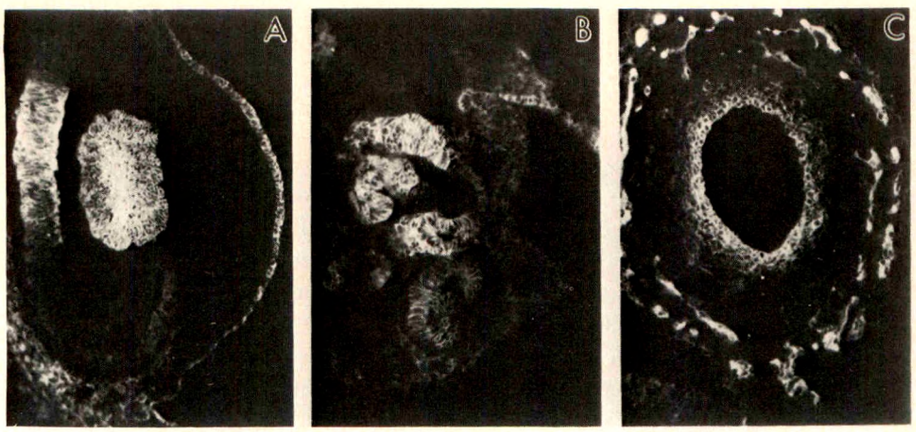

Fig. 3. Expression of N-CAM in tissues derived from all three germ layers.[25] **A**, N-CAM is expressed in retina, lens, and cornea of chicken eye at embryonic day 3; **B**, N-CAM in distal tubules of kidney at embryonic day 5; **C**, N-CAM on submucosa and ganglionic precursors in intestines at embryonic day 7. In most of these tissues N-CAM expression is markedly decreased as tissues mature, but N-CAM can be reexpressed in some tumors from these tissues, such as Wilms' tumor of the kidney.[119]

the proliferating lens epithelium. In kidney (Fig. 3, *B*) a series of cell adhesion molecule cycles is observed: L-CAM is seen on wolffian ducts (the inductor tissue) and, after induction, N-CAM appears on mesonephric mesenchyme; after induction, L-CAM appears on collecting tubules. In the formation of the gut (Fig. 3, *C*), N-CAM, as well as L-CAM, is seen in epithelia and then N-CAM disappears.[15, 25]

The importance of cell adhesion molecules in development is also emphasized by perturbation experiments with antibodies to specific cell adhesion molecules. Antibodies to N-CAM[84] or N-cadherin,[83] for example, perturb cell layers in retinal explants, whereas antibodies to Ng-CAM disrupt neurite fasciculation.[85] A variety of other such experiments shows that, in general, disruption of cell adhesion molecule binding alters morphologic features. Conversely, disruption of morphologic features can affect cell adhesion molecule expression, as seen, for example, when nerve-muscle interactions are disrupted. Myoblasts and myotubes express N-CAM, but after innervation of the muscle, N-CAM is down regulated and is barely detectable on muscle fibers. When the sciatic nerve is crushed or cut, levels of N-CAM messenger ribonucleic acid[86] and protein[87, 88] are markedly increased. Moreover, N-CAM and Ng-CAM expression are up regulated in the dorsal root ganglion of the affected segment and are down regulated in the ventral horn on the affected side.[88] After nerve regeneration, the normal patterns are restored.

Obviously the timing and regulation of cell adhesion molecule expression are critical processes for morphogenesis and for the maintenance of adult tissues. A variety of specific factors are also known to influence their expression. For example, estradiol enhances L-CAM expression in granulosa cells,[89] progesterone increases the expression of a cadherin in *Xenopus* oocytes,[90] and steroid hormones affect C-CAM (cell CAM-105) expression in rat uterus.[91] Nerve growth factor stimulates increased production of Ng-CAM/L1/NILE in PC12 cells[85, 92, 93] and Schwann cells[94]; it also can affect N-CAM levels in PC12 cells.[95, 96]

Several other agents have been shown to affect N-CAM expression. N-CAM levels were up regulated by treatment of embryonal cell lines with retinoic acid[97] and were down regulated when a rat neuroblastoma cell line was transfected with N-*myc*.[98] N-CAM expression in 3T3 cells has also been induced by transforming growth factor β.[99] Thyroidectomy leads to increased expression of N-CAM on the muscle surface, and the increase is reversed by thyroxine treatment.[100]

Cellular transfection

A variety of new information about cell adhesion molecules and their ability to influence other cellular processes has been obtained by transfecting cells with complementary deoxyribonucleic acid (cDNA) encoding specific cell adhesion molecules. The results have also verified previous analyses of cell adhesion molecule binding. For example mouse L cells, which do not express any known cell adhesion molecule, have been transfected with cDNA for a number of different cell adhesion molecules.[20, 71, 101-103, 139] In each case the specific cell adhesion molecule was synthesized and expressed on the cell surface. The transfected cells, unlike normal L cells, formed aggregates, and antibodies to the trans-

fected cell adhesion molecule blocked this aggregation. L-CAM-expressing cells[139] did not bind to N-CAM-expressing cells or to untransfected cells, verifying that L-CAM, like N-CAM, mediates cell adhesion by a homophilic mechanism.

Most cell adhesion molecules are transmembrane proteins, and a variety of data indicate that they interact with cytoskeletal elements. Actin filaments, for example, collect near boundaries between cells aggregated by L-CAM[20] or N-cadherin,[102] and spectrin binds to the large cytoplasmic domain form of N-CAM.[104] L-CAM interacts with cytoplasmic proteins called catenins,[105] and in extracts of MDCK cells it purifies with fodrin-ankyrin complexes.[106] Transfection with cell adhesion molecule cDNA has emphasized the significance of these interactions. For example, aggregation by cells transfected with L-CAM cDNA is reduced by cytochalasin D, which disrupts microfilaments, whereas aggregation of cells transfected with N-CAM cDNA is mildly decreased by nocodazole, which disrupts microtubules.[103] In addition, removal of as few as 30 amino acids from the carboxyl terminus of L-CAM destroyed its interaction with actin; the transfected cells did not aggregate even though they expressed truncated L-CAM on the cell surface.[103, 105, 107, 108]

As an extension of this approach, L-CAM/N-CAM chimeric cDNA that encoded the extracellular region of L-CAM coupled to the intracellular region of N-CAM was used.[103] As expected, cells expressing the L-CAM/N-CAM chimeric protein aggregated with the specificity of L-CAM but the aggregation was inhibited by nocodazole, which affects N-CAM binding, but not by cytochalasin D, which affects L-CAM binding. Cell adhesion molecule binding is thus influenced and can be regulated by cytoplasmic elements.

Transfected cells also reveal interactions between cell adhesion molecule binding and other cellular processes, such as junction formation by cell junctional molecules. The mouse sarcoma S180 cell line is a fibroblast-like cell that expresses no known cell adhesion molecule, aggregates weakly, if at all, and forms extremely few gap junctions or adherens junctions. When this cell line was transfected with L-CAM[20] or N-cadherin[102] cDNA, the cells aggregated via the specific cell adhesion molecule. Moreover, at confluence the cells were changed to a polygonal shape, formed an epithelioid sheet, and expressed significant numbers of adherens junctions and communicating gap junctions.

An important aspect of development is the sorting out of discrete populations of cells. Transfected cells provide a simplified, controlled system for examining the role of cell adhesion molecules in some aspects of these processes. In addition, cell sorting requires cell movement and is thus more complex than simple cell adhesion, so cell sorting assays can reveal other subtleties in cell adhesion molecule function. For example, cells expressing different cell adhesion molecules can sort from each other,[101, 109, 110] but so can cells expressing different amounts of the same cell adhesion molecule.[109] Similarly, cells expressing the L-CAM/N-CAM chimera described above bind to L-CAM-expressing cells but sort out from them and do not sort from untransfected cells[103]; presumably the cytoplasmic anchoring of the chimeric molecule is too weak to withstand the mechanical forces of cell sorting. The sorting of cells expressing two cell adhesion molecules from cells expressing one is complex[109] but appears to be directed by the levels of expression of the shared cell adhesion molecule. Cell adhesion molecules thus are critical to cell sorting, but factors such as levels of expression, cytoplasmic interactions, and the combination on any one cell are as important to this process as specificity.

Cell adhesion molecules in disease

The roles of cell adhesion molecules in disease and their potential use as diagnostic indicators are just beginning to be assessed, but a variety of conditions have already been found that involve changes in cell adhesion molecule expression. Alterations of N-CAM levels have been seen in degenerative disease, developmental defects, and toxic conditions.[13] For example, N-CAM levels were increased in the amniotic fluid of mothers carrying fetuses with neural tube defects,[111] and in one study N-CAM increased in the cerebrospinal fluid of patients with multiple sclerosis in parallel with their clinical improvement.[112] Cell adhesion molecule expression patterns are changed in a variety of muscular disorders, and resemble those seen in regenerating muscles.[113-115]

Both up and down regulation of cell adhesion molecules has been observed in tumors and transformed cells. N-CAM is down regulated in neural retinal cells transformed with Rous sarcoma virus,[116] and L-CAM (uvomorulin) is down regulated in MDCK cells transformed with Harvey or Moloney sarcoma viruses.[117] Moreover, the ability of the MDCK cells to invade collagen gels or heart explants increased with decreased L-CAM expression. Expression of L-CAM also has been shown to be inversely correlated with metastatic potential in sublines of the murine ovarian tumor line OV2944.[118] In contrast to these down regulations, N-CAM expression is increased in Wilms' tumor,[119] small cell lung carcinomas,[120-122] Ewing's sarcoma,[123] and human neuroblastoma,[120, 123, 124] and in most cases the embryonic form of N-CAM is expressed. In lung carcinomas[81] both L-CAM and P-cadherin are present in amounts and locations that parallel their expression in normal tissues, and they are detected at similar levels in lymph node metastases of these tumors.

Several molecules associated with tumor formation are members of the N-CAM family. These include the carcinoembyonic antigen,[125-128] the biliary glycoprotein BGP1,[129] melanoma antigen MUC18,[130] and a gene deleted in colon carcinoma (DCC).[131] Carcinoembyonic antigen is present in embryonic and transformed colonic epithelia and has been shown recently to be a cell adhesion molecule.[33] MUC18 is found on normal vascular smooth muscle[132] and on the surface of melanoma cells, where its appearance correlates with metastatic potential and poor prognosis. The DCC gene product has been postulated to be a tumor suppressor.[131, 133]

Overall the study of cell adhesion molecules in pathologic tissues promises to lead to a variety of new diagnostic reagents. It should also provide new insights into aspects of cell adhesion molecule function.

SPECIAL DELIVERY

For Endometriosis Patients

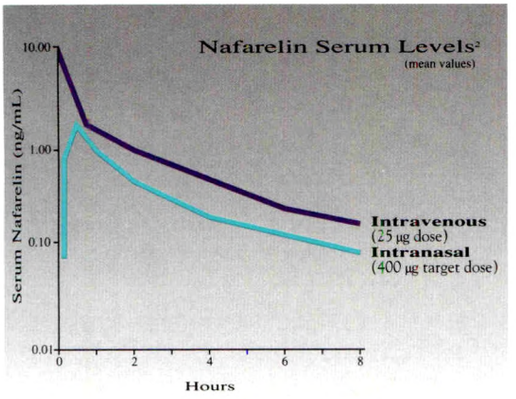
SYNAREL®

(NAFARELIN ACETATE)

NASAL SOLUTION, 2 MG/ML

Please see brief summary of prescribing

The Only GnRH* Agonist With The Dosing Distinction Of Intranasal Delivery



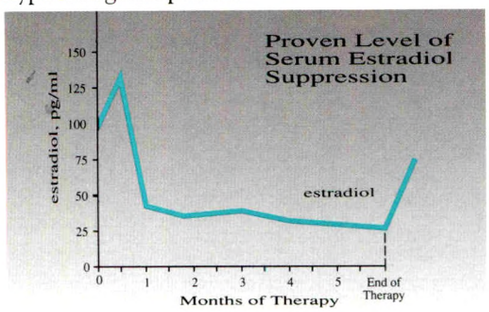
Of all the available treatment options for endometriosis, GnRH agonists are emerging as a preferred therapeutic option—and SYNAREL® (nafarelin acetate) is setting the pace.

One-of-a-kind intranasal administration

Unlike other GnRH agonists, SYNAREL is 200 times as potent as native GnRH—which is why SYNAREL can be administered in a highly accurate, controlled-dose intranasal form. Intranasal delivery is preferred by physicians[1†] for patient convenience, as well as for ease of patient management should allergic or adverse events occur.

Proven absorption for reliable control

In pharmacokinetic studies, SYNAREL was rapidly absorbed into systemic circulation following intranasal administration, with maximum serum concentrations achieved between



Intranasal administration produces nafarelin serum levels comparable to IV. dosing[2]

10 and 40 minutes. And, SYNAREL therapy was well tolerated, with a low incidence of nasal irritation (10%).

Outstanding resolution of symptoms

B.I.D. controlled-dose intranasal administration provides serum estradiol levels that result in outstanding clinical efficacy in the management of endometriosis, while producing minimal impact on bone and a predictable hypoestrogenic profile.[‡]

Serum estradiol concentration during treatment with SYNAREL 200 µg B.I.D. (n = 73)

In clinical studies, 94% of patients taking SYNAREL reported improvement of symptoms. Furthermore, 86% of patients taking SYNAREL showed improvement of endometriotic lesions (as measured by AFS scores) after the 6-month course of therapy.

Lowers estrogen without adding androgen

SYNAREL exhibits fewer masculinizing side effects than danazol. (The most frequent side effects are those of hypoestrogenism.)

The GnRH analog more and more physicians prescribe

Today, more and more physicians are prescribing SYNAREL for the management of endometriosis[3]—and more and more patients are experiencing the important clinical benefits intranasal SYNAREL has been proven to provide.

SYNAREL®

2. Syntex document #829-243-B.
3. Syntex document #829-243-C.

*Gonadotropin-releasing hormone analog.

†In a written survey conducted at the 38th Annual Meeting of the American College of Obstetricians and Gynecologists (May 1990), 299 physicians who prescribe GnRH analogs for the management of endometriosis were asked whether they preferred the intranasal or depot injection route of drug administration, and why.

‡ There is a small, largely reversible loss in bone density with 6-month treatment. Use of Synarel for longer than the recommended 6 months or in the presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Please see brief summary of prescribing information on last page.

The Only GnRH* Agonist With The Dosing Distinction Of Intranasal Delivery

B.I.D. controlled-dose intranasal administration offers important clinical benefits, including highly accurate metered-dose delivery and proven absorption through nasal mucosa. Pregnancy should be ruled out before therapy with SYNAREL is initiated, and patients should be advised to use a nonhormonal method of contraception when taking SYNAREL.

Intranasal administration provides serum estradiol levels that result in outstanding clinical efficacy in the management of endometriosis, while producing minimal impact on bone and a predictable hypoestrogenic profile.† Retreatment cannot be recommended since safety data for retreatment are not currently available.

Physician-preferred GnRH agonist delivery system for patient convenience.

Intranasal administration facilitates ease of patient management should allergic or adverse events occur.

For more information, please call: 1-800-727-0400

*Gonadotropin-releasing hormone analog.

† There is a small, largely reversible loss in bone density with 6-month treatment. Use of Synarel for longer than the recommended 6 months or in the presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

SYNAREL®
(NAFARELIN ACETATE)
NASAL SOLUTION, 2 MG/ML

Setting The Pace In Endometriosis Therapy

BRIEF SUMMARY

SYNAREL® Nasal Solution contains nafarelin acetate (2 mg/mL, expressed as nafarelin base), benzalkonium chloride, glacial acetic acid, sodium hydroxide or hydrochloric acid, sorbitol, and purified water.

INDICATIONS AND USAGE: For management of endometriosis. Experience is limited to women 18 years and older treated for 6 months.

CONTRAINDICATIONS: Hypersensitivity to GnRH, GnRH agonist analogs or any excipients in SYNAREL; undiagnosed abnormal vaginal bleeding; pregnancy or possibility of pregnancy while taking the drug because SYNAREL may cause fetal harm when administered to a pregnant woman. If SYNAREL is used during pregnancy or if the patient becomes pregnant while taking this drug, she should be apprised of the potential hazard to the fetus; use in women who are breast feeding.

WARNINGS: Safe use in pregnancy has not been established clinically. Before starting treatment pregnancy must be excluded.

When used regularly at the recommended dose, SYNAREL usually inhibits ovulation and stops menstruation. Contraception is not insured, particularly if patients miss successive doses. Therefore, patients should use nonhormonal contraception. Advise patients to see their physician if they believe they may be pregnant. If a patient becomes pregnant during treatment, discontinue the drug; apprise patient of the potential risk to the fetus.

PRECAUTIONS Information for Patients: 1. Since menstruation should stop with SYNAREL, the patient should notify her physician if regular menstruation persists. Patients missing successive doses may experience breakthrough bleeding.

2. Patients should not use SYNAREL if pregnant, breast feeding, have undiagnosed abnormal vaginal bleeding, or are allergic to any of its ingredients.

3. Safe use in pregnancy has not been established. Therefore, a nonhormonal method of contraception should be used during treatment. If a patient becomes pregnant during treatment, she should discontinue the drug and consult her physician.

4. Adverse events occurring most frequently in clinical studies are associated with hypoestrogenism. Nasal irritation occurred in about 10% of patients.

5. Induced hypoestrogenic state results in a small loss in bone density over a 6-month treatment course. Some of this loss may not be reversible. During one six-month treatment period, this should not be important. In patients with major risk factors for decreased bone mineral content, i.e., chronic alcohol and/or tobacco use, strong family history of osteoporosis, or chronic use of drugs that can reduce bone mass such as anticonvulsants or corticosteroids, SYNAREL may pose additional risk. In these patients risks and benefits must be weighed carefully. Repeated courses of treatment with GnRH analogs are not advisable in patients with major risk factors for loss of bone mineral content.

6. Patients with intercurrent rhinitis should consult their physician for use of a topical nasal decongestant. If a topical nasal decongestant is required during treatment, it must be used at least 30 minutes after SYNAREL dosing to decrease the possibility of reducing drug absorption.

7. Retreatment cannot be recommended since safety data beyond 6 months are not available.

Drug Interactions: No pharmacokinetic-based drug-drug interaction studies have been conducted. Nafarelin acetate is a peptide primarily degraded by peptidase and not by cytochrome P-450 enzymes, and is only about 80% bound to plasma proteins at 4°C; therefore drug interactions would not be expected to occur.

Drug/Laboratory Test Interactions: SYNAREL in therapeutic doses suppresses the pituitary-gonadal system. Normal function is usually restored 4-8 weeks after treatment is discontinued. Therefore, diagnostic tests of pituitary gonadotropic and gonadal functions during treatment and up to 4-8 weeks after discontinuation of SYNAREL may be misleading.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Carcinogenicity studies were conducted in rats and mice at intramuscular doses up to 110 times and 560 times the maximum recommended human intranasal dose, respectively. These multiples of the human dose are based on the relative bioavailability of the drug by the two routes of administration. As with other GnRH agonists, nafarelin acetate given to laboratory rodents at high doses for prolonged periods induced hyperplasia and/or neoplasia of endocrine organs. At 24 months, there was an increase in the incidence of pituitary tumors (adenoma/carcinoma) in high-dose female rats and a dose-related increase in male rats. There was an increase in pancreatic islet cell adenomas in both sexes, and in benign testicular and ovarian tumors in the treated groups. There was a dose-related increase in benign adrenal medullary tumors in treated female rats. In mice, there was a dose-related increase in Harderian gland tumors in males and an increase in pituitary adenomas in high-dose females. No metastases of these tumors were observed. It is known that tumorigenicity in rodents is particularly sensitive to hormonal stimulation.

Mutagenicity studies using bacterial, yeast, and mammalian systems provided no evidence of mutagenic potential.

Reproduction studies in male and female rats have shown full reversibility of fertility suppression when treatment was discontinued after continuous administration for up to 6 months.

Pregnancy, Teratogenic Effects: *Pregnancy Category X.* Intramuscular SYNAREL was administered to rats throughout gestation at about 0.5, 2, and 7 times the maximum recommended human intranasal dose based on the relative bioavailability by the two routes of administration. An increase in major fetal abnormalities was seen in 4/80 fetuses at the highest dose. A similar study at the same doses in rats and studies in mice and rabbits at doses up to 600 μg/kg/day and 0.18 μg/kg/day, respectively, failed to demonstrate an increase in fetal abnormalities after administration throughout gestation. In rats and rabbits, there was a dose-related increase in fetal mortality and a decrease in fetal weight with the highest dose.

Nursing Mothers: It is not known whether SYNAREL is excreted in human milk. Because many drugs are excreted in human milk, and because the effects of SYNAREL on lactation and/or the breastfed child have not been determined, SYNAREL should not be used by nursing mothers.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: The most frequently reported adverse reactions were those related to hypoestrogenism. In controlled studies comparing SYNAREL (400 μg/day) and danazol (600 or 800 mg/day), the following adverse reactions were most frequently reported and thought to be drug-related.

Hypoestrogenic: hot flashes (SYNAREL 90%, danazol 69%), decreased libido (22%, 7%), vaginal dryness (19%, 7%), headaches (19%, 21%), emotional lability (15%, 18%), insomnia (8%, 4%); **Androgenic:** acne (13%, 20%), myalgia (10%, 23%), reduced breast size (10%, 16%), edema (8%, 23%), seborrhea (8%, 17%), weight gain (8%, 28%), hirsutism (2%, 6%), increased libido (1%, 6%); **Local:** nasal irritation (10%, 3%); **Miscellaneous:** depression (2%, 5%), weight loss (1%, 3%).

Less than 1% of patients experienced paresthesia, palpitations, chloasma, maculopapular rash, eye pain, urticaria, asthenia, lactation, breast engorgement, and arthralgia. In clinical trials, immediate hypersensitivity thought to be possibly or probably related to nafarelin occurred in 3 (0.2%) of 1509 healthy subjects or patients.

Changes in Bone Density: After 6 months' treatment vertebral trabecular bone density and total vertebral bone mass, measured by quantitative computed tomography (QCT), decreased by an average of 8.7% and 4.3%, respectively, compared to pretreatment levels. There was partial recovery of bone density post-treatment; the average trabecular bone density and total bone mass were 4.9% and 3.3% less than pretreatment levels, respectively. Total vertebral bone mass, measured by dual photon absorptiometry (DPA), decreased by a mean of 5.9% at end of treatment. Mean total vertebral mass, re-examined by DPA 6 months post-treatment, was 1.4% below pretreatment levels. There was little, if any, decrease in the mineral content in compact bone of the distal radius and second metacarpal. Use for longer than the recommended 6 months or in presence of other known risk factors for decreased bone mineral content may cause additional bone loss.

Changes in Laboratory Values: *Plasma enzymes.* During clinical trials SGOT and SGPT levels were more than twice the upper limit of normal in only one patient each. There was no other evidence of abnormal liver function and levels returned to normal after treatment was stopped.

Lipids. At enrollment and at end of treatment, 9% of patients on SYNAREL 400 μg/day and 2% on danazol had total cholesterol values above 250 mg/dL.

Of those with pretreatment cholesterol values below 250 mg/dL, 6% on SYNAREL and 18% on danazol had post-treatment values above 250 mg/dL.

Mean (± SEM) pretreatment values for total cholesterol from all patients were 191.8 (4.3) mg/dL in the SYNAREL group and 193.1 (4.6) mg/dL in the danazol group. At the end of treatment, mean values from all patients were 204.5 (4.8) mg/dL in the SYNAREL group and 207.7 (5.1) mg/dL in the danazol group. These increases from pretreatment values were significant ($p < 0.05$) in both groups.

Triglycerides were increased above the upper limit of 150 mg/dL in 12% of the patients on SYNAREL and in 7% of the patients on danazol.

At the end of treatment, no patients on SYNAREL had abnormally low HDL cholesterol fractions (< 30 mg/dL) compared with 43% of patients on danazol. No patients on SYNAREL had abnormally high LDL cholesterol fractions (> 190 mg/dL) compared with 15% of those on danazol. There was no increase in the LDL/HDL ratio in patients on SYNAREL, but approximately a 2-fold increase in the LDL/HDL ratio in patients on danazol.

Other changes. In comparative studies, the following changes were seen in approximately 10% to 15% of patients. SYNAREL was associated with elevations of plasma phosphorous and eosinophil counts, and decreases in serum calcium and WBC counts. Danazol therapy was associated with an increase of hematocrit and WBC.

OVERDOSAGE: At present there is no clinical evidence of adverse effects following overdosage of GnRH analogs.

Periovulatory calcium channel blockade enhances reproductive performance in an animal model for endometriosis-associated subfertility

Alex Steinleitner, MD, Hovey Lambert, PhD, Mariluz Suarez, BS, Nurys Serpa, BS, Beverly Robin, BS, and Bernard Cantor, MD

Miami Beach, Florida

Current evidence suggests that peritoneal inflammatory cell hyperactivation may be the essential pathologic abnormality in patients with endometriosis-associated subfertility. In these experiments we utilized an animal model to evaluate the use of an immunomodulatory agent as an alternative treatment for endometriosis-associated subfertility. The right uterine horn of 12 golden hamsters was resected and 2 × 2 mm squares were explanted onto the left uterine mesentery. Controls included hamsters undergoing uterine horn resection without endometrial explantation ($n = 6$) and nonsurgically treated animals ($n = 6$). Ovulation induction was initiated 6 weeks postoperatively with 40 IU of pregnant mare's serum gonadotropin on day 1 and 40 IU of human chorionic gonadotropin on day 3. Groups of six explant-bearing hamsters and six nonsurgical control hamsters were treated with verapamil (250 μg/kg every 8 hours subcutaneously), a calcium channel–blocking agent known to inhibit macrophage activation, from day 1 to 48 hours after administration of human chorionic gonadotropin. Animals were then killed and the number of embryos and oocytes in left tube counted as a reflection of reproductive performance. Fertilization was completely inhibited in animals bearing uterine explants. Treatment with verapamil dramatically reversed this effect. These data suggest that periovulatory treatment with an immunomodulatory agent such as verapamil may be an effective alternative to conventional treatment for endometriosis-associated subfertility. (Am J Obstet Gynecol 1991;164:949-52.)

Key words: Endometriosis, calcium channel blockade, verapamil, infertility

Contemporary thought in reproductive endocrinology holds that aberrations in intraperitoneal nonspecific immunity may be the essential pathologic entity contributing to subfertility in patients with minimal or mild endometriosis.[1] This hypothesis is supported by the finding of increased numbers of activated peritoneal inflammatory cells[2] and elevated levels of gametotoxic inflammatory mediators[3, 4] in the peritoneal fluid of patients with endometriosis when compared with fertile controls. However, despite increasing acceptance of these findings as the etiologic basis for endometriosis-associated subfertility, therapy for these patients continues to be based on the medical or surgical eradication of endometriotic implants.

In this article we describe experiments that explore an alternative approach to the treatment of impaired early reproductive performance in endometriosis, using the calcium channel–blocking drug verapamil as an immunomodulatory agent to reduce intraperitoneal inflammatory cell activation in an animal model for endometriosis-associated subfertility.

Material and methods

Experimental procedures used in this study were based on rodent models for endometriosis-associated subfertility described by Golan[5] and Kaplan et al.[6] All animals were maintained on a constant 14-hour-light/10-hour-dark cycle, fed standard laboratory chow, and given water as desired for 7 to 10 days before use in these studies. Animal care procedures were reviewed by the Animal Reseach and Medical Research Committees of Mount Sinai Medical Center (Miami Beach) and were performed in accordance with the standards set in the *NIH Guide for Care and Use of Laboratory Animals.*

Sexually mature female golden hamsters (6 weeks old, 150 gm, Harlan Sprague-Dawley, Indianapolis) were used in a model for surgically induced pelvic endometriosis. Midline laparotomies were performed with animals under pentobarbital anesthesia; prophy-

lactic antibiotics (0.1 mg of penicillin G) were given and a clean, but not sterile, technique was used. At laparotomy the right uterine horn was excised, and care was taken to preserve the right ovary. The excised uterine horn was opened longitudinally and cut into four 2 × 2 mm specimens. In 12 animals an endometriosis-like lesion was induced by suturing the excised uterine specimens onto the left uterine mesentery with 6-0 nylon sutures. An additional six animals served as surgical controls, undergoing resection of the right uterine horn without subsequent explantation. In each instance incisions in the hamsters were closed in two layers with 4-0 polyglycolic acid sutures, and the animals were returned to the vivarium for observation.

Six weeks after operation all hamsters were subjected to ovulation induction with 40 IU of pregnant mare's serum gonadotropin on cycle day 1, followed by 40 IU of human chorionic gonadotropin on day 3. Hamsters bearing uterine explants were randomly divided into two groups for treatment with subcutaneous injections of either verapamil (250 μg/kg) or vehicle (phosphate-buffered saline solution), given every 8 hours starting with the initiation of ovulation induction. Concurrently, ovulation induction was begun in 12 animals that had not undergone surgery; groups of six animals were treated with either verapamil or phosphate-buffered saline solution injections, as described above.

Immediately after treatment with human chorionic gonadotropin hamsters were placed in individual mating chambers for 48 hours with male animals of established fertility. Subsequently, all animals were killed by cervical dislocation for collection of the left uterine horn. Injections of study medications (verapamil, vehicle) were continued until the time of death. Unfertilized oocytes and embryos were flushed from the left uterine horn and counted as a reflection of reproductive performance.

Nonparametric statistics (Kruskal-Wallis, Mann-Whitney U tests) were used to compare the number of oocytes and embryos and the rates of fertilization in the various experimental groups. All data are reported as the mean ± SEM.

Results

Surgical procedures, ovarian hyperstimulation, and verapamil treatment were well tolerated by all animals. The entire complement of hamsters was available for analysis in this experiment.

Number of gametes flushed from the left uterine horn of hamsters treated with simple excision of the right uterine horn (17.2 ± 0.9) was not different from that of saline solution–treated (16 ± 1.5) or verapamil-treated (18.8 ± 1.4) nonsurgical controls. Fertilization rates were 100% in these groups. In contrast, autologous explantation of resected uterine tissue to the left uterine mesentery completely inhibited fertilization (0%). Ovulation was not affected in these hamsters (17.3 ± 1.5 nonfertilized oocytes per animal). Periovulatory treatment with verapamil entirely reversed the effect of surgically induced endometriosis on fertilization. Number of embryos (19.5 ± 1.8) and fertilization rate (100%) in these animals were not different from those of surgical and nonsurgical controls.

Comment

Current evidence suggests that subfertility in patients with minimal or mild endometriosis results from an adverse effect of activated immunocompetent cells on early reproductive events. Data supporting this hypothesis include the finding of increased numbers of activated peritoneal macrophages and lymphocytes in patients with endometriosis.[1, 2] Activated peritoneal macrophages have been found to specifically inhibit fertilization in animal models.[7] Peritoneal fluid from patients with endometriosis has been shown to contain elevated levels of gametotoxic inflammatory mediators (e.g., interleukin-1,[4] tumor necrosis factor[3]) and to inhibit gamete interaction and embryo development in both in vitro[8, 9] and in vivo models.[10] Recent evidence suggests that the aberrant peritoneal inflammatory environment may be a consequence of the production of complement factor 3 (a potent inflammatory mediator) by endometriotic implants.[11]

In spite of this evolving understanding of the pathophysiologic profile of endometriosis-associated subfertility, current approaches to the treatment of endometriosis-associated subfertility remain empiric and are based on the eradication of visible endometriotic implants. In many instances these therapies have proved unsatisfactory to both patient and practitioner. Medical suppression of endometriotic implants entails the use of medications that impart undesirable side effects (e.g., danazol, gonadotropin-releasing hormone agonists). Patients must forgo attempting conception for the duration of the suppression cycle. Subsequent recurrence of endometriosis is common.[12] It is important that neither medical nor surgical eradication of stage I or stage II endometriosis has been shown to be superior to expectant management in controlled trials.[13-16] The need to develop effective treatment modalities not limited by these restrictions is evident.

Studies in our laboratory have focused on the use of immunomodulatory agents as an alternative means of treating endometriosis-associated subfertility. In this study we evaluated the effect of calcium channel blockade on the inhibition of early reproductive performance associated with uterine explantation in the hamster model for endometriosis. Although calcium channel–blocking agents are not classic "antiinflammatory drugs," drugs of this class are known to exert

diverse effects on leukocyte function. Macrophage activation is inhibited by verapamil and nifedipine in vitro.[17] Macrophage cytolytic factor[18] and concanavalin A–stimulated superoxide ion[19] production is reduced by verapamil and its analogs. Production of interferon gamma is diminished by most calcium antagonists.[20] Lymphocyte migration induced by interleukin-1 and interleukin-8 is markedly inhibited by calcium blockade in vitro.[21] T-cell proliferation,[22] activation,[23] and capping[24] are impaired by a variety of calcium channel blockers. Natural killer activity is reduced in the presence of both verapamil and nifedipine.[25]

The data obtained in this study demonstrate calcium blockade to be an effective means of abrogating the adverse influence of uterine explants on early reproductive performance in this model. Periovulatory verapamil administration resulted in a complete reversal of the inhibition of fertilization observed in vehicle-treated hamsters. Ovulation was not affected in these animals. It is significant that this activity is not restricted to drugs with calcium channel–blocking properties. We have obtained similar results after periovulatory administration of the methylxanthine analog pentoxifylline in the murine syngeneic macrophage transfer model for endometriosis–peritoneal fluid environment[26] and in a hamster model identical to that used in this study.[27] We hypothesize that this phenomenon is the result of immunomodulation of intraperitoneal inflammatory activity, resulting in a consequent inhibition of monokine and lymphokine production or cell-mediated immune events responsible for impaired reproductive performance.

Although these early data are provocative, it is premature to suggest that these agents be used in clinical practice. Drugs used as immunomodulators in reproductive medicine must meet stringent criteria. Immunomodulatory agents must reduce inflammatory cell activity without adversely affecting ovulation, tubal motility, or nidation. Medications must be known to have minimal teratogenic potential. Ideally, agents should be free from noxious side effects. Until an appropriate agent has been thoroughly evaluated for safety and efficacy in a controlled clinical trial, we would recommend restraint in the application of these drugs for the routine treatment of patients with endometriosis.

In summary, these preliminary animal data provide a paradigm for an alternative approach to the treatment of endometriosis-associated subfertility, which is directed to the essential pathophysiologic parameters of this condition. Treatment with immunomodulatory agents holds the potential for supplying a safe and effective means of enhancing fertility without subjecting patients to the noxious side effects of contemporary treatment modalities. Further study of appropriate immunomodulators in the treatment of endometriosis-associated subfertility is indicated.

Discussion

Dr. Roland A. Pattillo, Milwaukee, Wisconsin. Your observation of verapamil-induced enhanced fertility is indeed of interest, and I commend you on this exciting finding and article.

Did you measure natural killer cell activity and was it altered as you indicated that decrease in natural killer cell activity may indeed be associated with the immunomodulatory effects that were observed?

Dr. Steinleitner (Closing). At this point we have not measured natural killer cell activity or the activity of other immunocompetent cells in our model, because of the limitations of our present laboratory.

I think it's important to note that in 1990 we don't know what the principal effector cell is. However, if we use an immunomodulator that has broad specificity, then it is possible to treat this in an, if you will, empiric fashion, going after all possible effectors of this condition.

Make researching easier with the Ten-Year Cumulative Index (1978-1987) to the American Journal of Obstetrics and Gynecology

The Ten-Year Cumulative Index is a complete guide to more than 30,000 pages of original articles, case reports, letters, and editorials published in the American Journal of Obstetrics and Gynecology from 1978 through 1987 (volumes 130 to 157). Numbering more than 800 pages, the Cumulative Index includes both a subject and an author index. This hard-cover volume is $64.50 ($69.00 international). Macrophage-conditioned media enhance endometrial stromal cell proliferation in vitro

David L. Olive, MD, Iris Montoya, BS, Robert M. Riehl, PhD, and Robert S. Schenken, MD

San Antonio, Texas

It has been hypothesized that the activated peritoneal macrophages of endometriosis, rather than being a response to ectopic endometrium, may contribute to its pathogenesis. This study attempts to define the effect of macrophage-derived growth factors on endometrial stromal cell growth in vitro, as well as the interaction between estrogen and these growth factors. Mouse endometrial stromal cells were prepared and cultured in either a serum-containing, insulin-free medium or a serum-free, insulin-containing medium, and the effects of adding 10% macrophage-conditioned medium on [^{3}H]thymidine incorporation were assessed. Results indicate that macrophage-conditioned medium will increase incorporation in the presence of insulin but not in insulin-free media. Serum can substitute for macrophage-conditioned medium, but the two together show no additive or synergistic effect. The effect of estrogen on this system was determined, and results indicate that estrogen will perform the function of insulin, with an optimal concentration of 10^{-10} to 10^{-12} mol/L. Thus macrophage-conditioned medium appears to function as a competence growth factor, and estrogen (in appropriate concentrations) functions as a progression growth factor. (Am J Obstet Gynecol 1991;164:953-8.)

Key words: Macrophage, endometriosis, estrogen, stromal cell

Endometriosis, a gynecologic disorder involving ectopic growth of endometrial tissue, has long been tied to immunologic abnormalities. Several investigators have identified an abnormality of peritoneal macrophages in such women, demonstrating an increase in macrophage number[1, 2] and activation level[2] in association with the disease. Additional studies[2, 3] have reported excessive production of macrophage secretory products in the presence of endometriosis.

A prevalent hypothesis has been that the ectopic endometrium incites an intraperitoneal inflammatory response, resulting in recruitment and differentiation of peritoneal macrophages. However, a recent longitudinal study[4] in the rabbit calls this theory into question by failing to demonstrate a change in macrophage number or function after induction of experimental endometriosis. Thus, whereas an association between endometriosis and abnormal macrophage function exists, no direct cause-and-effect relationship has been established.

An alternative hypothesis is the converse: A primary disorder of macrophage number or function may contribute directly to ectopic endometrial growth. Macrophage-derived growth factors that enhance the growth of fibroblast cell lines in vitro have been identified.[5, 6] In addition, women with endometriosis have been shown to possess peritoneal macrophages with excessive secretion of such growth factors.[7]

In this study we propose to define the effect of macrophage-derived growth factors on endometrial stromal cell growth in vitro. We have further sought to characterize the exact role of such factors in the cell growth process. Our results suggest that macrophage-derived growth factors function as competence factors, allowing endometrial stroma to respond to mitogenic influences by increasing their rate of proliferation.

Material and methods

Animals and cell lines. Three- to five-month-old C57BL/6J mice and 8- to 12-month-old C3H/Hej mice (Jackson Laboratory, Bar Harbor, Me.) were used for harvesting peritoneal macrophages. Uterine tissue was obtained only from the C57BL/6J animals. The P388D$_1$ murine cell line (American Type Culture Collection, Rockville, Md.) was used for production of macrophage-conditioned media.

Chemicals. Nutridoma-SP media and insulin were purchased from Boehringher-Mannheim Biochemicals (Indianapolis). L-Glutamine, sodium pyruvate, gentamicin, and RPMI 1640 powdered media with phenol red were purchased from Hazelton Biologics, Inc. (Le-

nexa, Kan.). HEPES buffer and RPMI 1640 powdered media, phenol red free, were purchased from Irvine Scientific (Santa Ana, Calif.). Sodium chloride, potassium chloride, sodium bicarbonate, potassium orthophosphate, calcium chloride monohydrate, sodium lactate, glucose, bovine serum albumin, activated Norit-A charcoal, β-estradiol, deoxyribonuclease I, and phenol red solution were purchased from Sigma Chemical Corporation (St. Louis). Magnesium sulfate heptahydrate and sodium pyruvate were purchased from Fisher Scientific (Fair Lawn, N.J.). Dextran T-70 was purchased from Pharmacia LKB Biotechnology (Piscataway, N.J.), and defined fetal calf serum was obtained from Hyclone Laboratories (Logan, Ut.). Collagenase was purchased from Cooper Biochemical Corporation (Malvern, Pa.). [^{3}H]Thymidine was obtained from ICN Radiochemicals (Irvine, Calif.). Peptone was purchased from Difco Laboratories (Detroit).

Media preparation. The media used for isolation of endometrial stromal cells were modified Brinster's medium,[8] pH 7.2, consisting of 115.48 mmol/L sodium chloride, 4.78 mmol/L potassium chloride, 1.19 mmol/L, 25 mmol/L sodium bicarbonate, 1.19 mmol/L magnesium sulfate, 20 mmol/L heptahydrate lactic acid, 0.5 mmol/L sodium pyruvate, 5.5 mmol/L glucose, and 5 gm/L bovine serum albumin.

For cell culture and proliferation assays, Nutridoma-SP (a serum-free medium containing insulin) was prepared with phenol red–depleted RPMI 1640, 1 mmol/L L-glutamine, 1 mmol/L sodium pyruvate, 10 to 25 mmol/L HEPES buffer, 25 μg/ml gentamicin, and 0.1% Nutridoma-SP base.

RPMI 1640 media for cell culture and proliferation assays consisted of 1 package of RPMI 1640 powder per liter of Millipore-filtered water, plus 2 gm sodium bicarbonate, pH adjusted to 7.3. When used for culture, 10% fetal bovine serum was added to produce a serum-containing medium without insulin.

Serum samples were stripped of sex steroids by addition of 10 mg/ml Dextran-T70 and 100 mg/ml Norit-A charcoal overnight at 4° C. The next morning the serum was filtered through 0.45, 0.2, and 0.1 μm filters into sterile containers and stored at 4° C.

Isolation of endometrial stromal cells. Endometrial stroma were isolated by a modification of the method of Riehl et al.[9] Briefly, the mice were put to death by cervical dislocation, and uteri were excised and placed immediately into modified Brinster's medium at 24° C. Fat and connective tissue were removed and the uteri were separated into individual horns. Each uterine horn was everted and placed into a 125 ml Erlenmeyer flask containing modified Brinster's medium with 1% (wt/vol) bovine serum albumin previously added. Each flask was gently agitated to remove dead cells and debris from the mucosal surface. Each horn was then removed with forceps and placed into a 50 ml test tube containing modified Brinster's medium, plus 1 mg/ml collagenase, 0.05% (wt/vol) deoxyribonuclease, and 0.5 mmol/L calcium chloride. The tubes were secured, immersed in a water bath at 37° C, and agitated for 30 minutes. At the end of the digestion period, each horn was drawn 25 times into the plastic tip of a 5000-P Pipetman (Rainin Instrument Co., Emeryville, Calif.) that had been cut to increase the bore diameter of the tip just large enough to accept the uterine horn. The solution was then filtered to remove epithelial cells. The uterine horn was then placed in 5 ml of fresh enzymatic solution, secured in a water bath, and agitated for 30 minutes. The horns were then drawn through the pipette tip 25 times, and the tube was again agitated for 30 minutes. The solution was then filtered and stromal cells were recovered. These cells were then washed twice in modified Brinster's media plus 1% bovine serum albumin.

Preparation of macrophage-conditioned media. Resident peritoneal macrophages were collected from C57BL/6J mice after cervical dislocation and rapid entry into the peritoneal cavity, where free fluid was collected and the cavity was washed with RPMI 1640. Peptone-stimulated peritoneal macrophages were induced by intraperitoneal injection of 1.0 ml 10% peptone into C57BL/6J and C3H/Hej mice. Three days later the animals were killed and the cells were collected as previously described.

All macrophages and the P388D$_1$ murine macrophage-like cell line were plated at 10^5 cells/ml in Nutridoma medium and incubated 72 hours. Culture supernatants were then collected, passed through a 0.4 μm filter, and stored for later use at −20° C.

Proliferation assay. Endometrial stromal cells, once isolated, were added to 96-well microliter plates (Corning Industries, Corning, N.Y.) at concentrations of 5×10^3 to 10^5 cells per well. In most cases the cells were immediately treated with an experimental medium, but in some experiments they were cultured for 24 hours in Nutridoma medium before addition of experimental media. Forty hours after exposure to an experimental medium, [^{3}H]thymidine was added and the cells were cultured an additional 8 hours. The wells were then washed in a Mini-Mesh II irrigation-aspiration system (MA Bioproducts, Walkersville, Md.) and the cells were filtered. Incorporated [^{3}H]thymidine was counted with a Tri-Carb 460C liquid scintillation system (Packard Instrument Company, Meridan, Conn.). All assays were performed in triplicate or quadruplicate.
